From a more general viewpoint, Masters and Johnson (1975; Masters et al., 1992) concluded that most sexual dysfunctions are due to crippling fears, attitudes, and inhibitions concerning sexual behavior, often based on dysfunctional early learning and then exacerbated by later aversive experiences. In another review of the accumulated evidence, however, Beck and Barlow (1984) played down the role of anxiety per se—which under some circumstances can actually enhance sexual performance in normally functioning men and women (Barlow, Sakheim, & Beck, 1983; Hoon, Wincze, & Hoon, 1977; Palace & Gorzalka, 1990). For example, when Barlow and colleagues (1983) told sexually functional male subjects in a laboratory experiment that there was a 60 percent chance of receiving electric shock while watching an erotic film unless they had an average-sized erection, these men actually showed *more* sexual arousal to the film than did men who were not threatened with shock. Instead of anxiety per se, Beck and Barlow emphasized that it is the cognitive distractions frequently associated with anxiety in dysfunctional people that seem to interfere with their sexual arousal. For example, Abrahamson and colleagues (1985) found that nondysfunctional men who were distracted by material they were listening to on earphones while watching an erotic film showed *less* sexual arousal than did men who were not distracted. The distraction in this study had nothing to do with anxiety but it nonetheless interfered with sexual arousal in normal men. Barlow and colleagues believe that sexually dysfunctional men and women get distracted by negative thoughts about their performance during a sexual encounter (such as "I'll never get aroused" or "She will think I'm inadequate"). It seems to be this preoccupation with negative thoughts, rather than anxiety per se, that is responsible for inhibiting sexual arousal. Thus, cognitive factors such as negative thoughts about performance have powerful effects on the physiology of sexual arousal. Another study consistent with this theory (Abrahamson, Barlow, & Abrahamson, 1989) confirmed that dysfunctional men with erectile problems differ from functional men in being more easily distracted by cues about their performance, resulting in smaller erections during erotic stimulation. Such self-defeating thoughts not only decrease his pleasure, but also can increase his anxiety if the erection does not happen (Malatesta & Adams, 1993), and this in turn can fuel further negative self-defeating thoughts.

**Interpersonal Problems** Interpersonal problems may cause a number of sexual dysfunctions (Malatesta & Adams, 1993; Masters et al., 1992). Lack of emotional closeness and poor communication can lead to erectile or orgasmic problems. An individual may be in love with someone else, may find his or her sexual partner physically or psychologically repulsive, or may have hostile feelings from prior misunderstandings, quarrels, and conflicts. A one-sided interpersonal relationship—in which one partner does most of the giving and the other most of the receiving—can lead to feelings of insecurity and resentment with resulting impairment in sexual performance (Friedman, 1974; Leiblum & Rosen, 1989a; Lobitz & Lobitz, 1978; Simon, 1975).

For a woman, lack of emotional closeness often appears to result from intercourse with a partner who is a sexually selfish and insensitive—rough, unduly hasty, and concerned only with self-gratification. As Kaplan (1974) pointed out, "Some persons have as much difficulty giving pleasure as others do in receiving it. These individuals don't provide their partners with enough sexual stimulation because they lack either the knowledge and sensitivity to know what to do, or they are anxious about doing it" (p. 78). In other instances, an individual may be hostile toward and not want to please his or her sexual partner. This situation seems to occur rather frequently in unhappy marital or other intimate relationships. In such relationships, channels of communication have largely broken down and sexual relations continue as a sort of habit or duty or simply to gratify one's own sexual needs.

**Changing Male-Female Roles and Heterosexual Relationships** An increase in erectile problems was reported during the 1970s, and a number of investigators hypothesized that this was related to two phenomena occurring during that period: (a) the increasing changes being achieved by the women's movement in our society, and (b) the growing awareness of female sexuality (Burros, 1974; Heiman & Grafton-Becker, 1989; Leiblum & Rosen, 1989b). These trends have led women to want and expect more from their lives, including their sexual relationships. Women no longer accept the older concept of being the passive partner in sex, and many are taking a more assertive and active role in sexual relations. This new role appears to threaten the image some men have of themselves as the supposedly "dominant" partner who takes the initiative in sexual relations (Steinmann & Fox, 1974). Some men appear to regard sexually assertive women who play an active role in sex as "castrating females" (Kaplan, 1974). In addition, there was speculation that women's greater assertiveness and higher expectations make many men feel that they are under pressure to perform. In spite of all this speculation about the effects of changes in women's roles on male sexual dysfunction, it should be noted that there is no good research supporting these hypotheses.

Changing male-female roles in heterosexual relationships also place greater demands on women. The expectation of taking an active rather than a passive role may cause a woman to make unrealistic demands on her own sexual responsiveness. Such demands may lead to some degree of unfulfilled desires, confusion, and self-devaluation, which in turn impair actual sexual performance. This situation seems especially true when a woman assumes a "spectator role" and almost literally monitors her own sexual performance, thus depriving it of spontaneity and naturalness.

Finally, our enhanced awareness of sexually transmitted diseases—fueled by the AIDS epidemic—has added an increment of anxiety to many sexual encounters both casual and otherwise (Katz, Frazer, & Wilson, 1993; Leiblum & Rosen, 1989b). The relatively carefree sexuality of the 1960s and 1970s has increasingly given way to concerns about "safe sex" with partners whose sexual (and drug-use) histories place them outside of the known high-risk groups. Several recent surveys in the United States and several European countries suggest that monogamy is the norm for most. For example, each found that between two-thirds and three-quarters of men reported having no more than one sexual partner in the past year, and only 3 percent of men reported five or more partners in the past year (9 percent of never married men had five or more partners in the past year) (Michael et al., 1994). In addition, the condom, once widely rejected as inhibiting spontaneity (or the appearance of it) and decreasing pleasure, is now heralded as essential equipment for many prudent adolescents and young adults—men and women—who are not in committed monogamous relationships. One study of college-age women reported that the percentage of women reporting that their partners used condoms during sex increased from 12 percent in 1975 to 41 percent in 1989 (Debuono et al., 1990). This was in spite of the fact that over the same time period the average number of sex partners for these college-age women did not change. In short, we are clearly in the midst of a new sexual revolution, one involving life and death decisions. It is still too early to tell what effect these dramatic changes will have on the incidence and prevalence of sexual dysfunctions. Conceivably, the added anxiety and suspicion created by the AIDS epidemic will be counterbalanced by the positive effects that may come with expectations of more enduring and committed relationships.

## Treatments and Outcomes

The treatment of sexual dysfunctions, too, has undergone nothing less than a revolution in the past 25 years. Once regarded as difficult and intractable therapeutic challenges, most sexual dysfunctions are now readily treated. Modern techniques include direct methods of attack on the dysfunctions themselves, usually with high levels of gentle and affectionate partner participation. For example, a couple may be given instruction and guided practice in overcoming, by vigorous stimulation, orgasmic inhibition in one of the partners; or vaginismus may be treated with intravaginal insertion, by the partner, of cylindrical objects of gradually increasing circumference until the excessive vaginal contractions cease. As a result of these newer approaches, success rates approaching 90 percent or more for some dysfunctions have become quite routine (Kaplan, 1987; Leiblum & Rosen, 1989a; LoPiccolo & Stock, 1986; Masters et al., 1992; Tollison & Adams, 1979; Wincze & Carey, 1991; Zilbergeld & Kilmann, 1984).

The turning point in sex therapy is uniformly considered to be the publication in 1970 of Masters and Johnson's *Human Sexual Inadequacy*, the product of an 11-year search to develop truly effective

*Sensate focus exercises are commonly used in the treatment of several different types of sexual dysfunction. In the first stage of such exercises, couples are instructed to touch any part of their partner's body except for the genital or breast areas. The goal at this stage is not to be sexual but rather to become aware of a wide range of touch sensations, both while touching and while being touched. At a later stage these exercises are expanded to include touching breasts and genitals, although sexual intercourse is still prohibited.*

treatment procedures for the common dysfunctions, both male and female. The success rates claimed by this team of dedicated clinical researchers astonished the professional community and rapidly led to the widespread adoption of their general approach, which combined elements of traditional therapy and behavior therapy in a framework emphasizing, as already noted, direct intervention aimed at the dysfunctions themselves.

Although the early confidence inspired by Masters and Johnson's reported results has waned somewhat (Beck, 1992; Leiblum & Pervin, 1980; Leiblum & Rosen, 1989b; LoPiccolo & Stock, 1986; Vandereycken, 1982; Wincze & Carey, 1991; Zilbergeld & Evans, 1980), their work has unquestionably encouraged a host of new therapeutic techniques. Despite differences in emphasis and methods, there seems to be general agreement on the importance of removing crippling misconceptions, inhibitions, and fears, and on fostering attitudes toward sexual behavior as a pleasurable, natural, and meaningful experience.

Because of the manner in which sexual dysfunctions are presented and described by those suffering from them, it is easy to lose sight of a crucial issue emphasized by Masters and Johnson and by virtually all those who have followed in their footsteps: Most sexual dysfunctions are not normally disorders of individuals, but rather of relationships between individuals. Thus the new treatments for sexual dysfunctions typically involve both partners. Joseph LoPiccolo (1978) put it this way:

> It must be stressed that all sexual dysfunctions are shared disorders; that is, the husband of an inorgasmic woman is partially responsible for creating or maintaining her dysfunction, and he is also a patient in need of help. Regardless of the cause of the dysfunction, both partners are responsible for future change and the solution of their problems. (p. 3)

With competent treatment, success rates vary between approximately 30 and 100 percent, depending in part on the individual or couple and on the nature of the problem. For example, Masters and Johnson (1970) and Kaplan (1975) reported success rates approaching 100 percent for the treatment of premature ejaculation and vaginismus, but considerably lower rates for male erectile and female orgasmic dysfunctions. More recent reviews (Andersen, 1983; Leiblum & Rosen, 1989a; LoPiccolo & Stock, 1986; Zilbergeld & Kilmann, 1984) essentially confirm these relative outcome expectancies, with one recent study suggesting that approximately 70 percent of men with erectile disorder show significant improvement with treatment (Hawton, Catalan, & Fagg, 1992). Moreover, there is an important distinction between lifelong and situational female orgasmic dysfunction. Treatment of the former, typically beginning with instruction and guided practice in masturbating to orgasm, has a high likelihood of success, while "situational" anorgasmia (where a woman may experience orgasm in some situations, with certain kinds of stimulation, or with certain partners, but not under the precise conditions she desires) often proves more difficult to treat, perhaps in part because it is often associated with relationship difficulties that may also be difficult to treat (Beck, 1992).

The somewhat more treatment-resistant erectile disorders probably reflect underlying contributory medical problems, the prevalence of which was seriously underestimated until recently. Sex therapy can be useful in many of these cases because psychological factors often interact with physiological factors in producing the dysfunction (Hawton et al., 1992). Nevertheless, as noted by Mohr and Beutler (1990), the only available recourse for these disorders may be the use of some sort of mechanical aid. Inflatable penile prostheses often prove preferable to implanted prostheses that maintain a constant rigidity, despite the potential disruption the need to inflate them may entail. The combination of a vacuum device (which draws blood into the spongy tissue of the penis) and constricting rubber or plastic ring at the base of the penis (which keeps it there under pressure) also shows considerable promise for some men whose erectile problems prove resistant to psychological or medical treatments.

## UNRESOLVED ISSUES

### on Long-Term Consequences of Childhood Sexual Abuse

Many studies during the past decade have linked recollections of childhood sexual abuse with adult psychopathology. Typically, the studies have compared the prevalence of abuse memories in patients (usually women) with and without a certain diagnosis. For example, a study might compare the prevalence of memories of childhood sexual abuse in women with borderline personality disorder to that in women with other personality disorders. The best-established associations between childhood sexual abuse and adult disorders are with borderline personality disorder (Chapter 9) and dissociative identity disorder (Chapter 7). Relevant studies are often interpreted as showing that childhood sexual abuse is a causal factor in the disorders (Anderson et al., 1993; Paris, Zweig-Frank, & Guzder, 1994; Sanders & Giolas, 1991; Waller, 1994; Glod, 1993; Whitman & Munkel, 1991); however, the available evidence is insufficient to establish a causal link. This is because establishing causation on the basis of retrospective studies is fraught with methodological perils, and furthermore, a number of other plausible interpretations of the findings have not been excluded.

First, consider the association between childhood sexual abuse and borderline personality disorder (discussed in Chapter 9). Although early sexual abuse may well cause the personality disorder, a number of other explanations of the association are also conceivable. For example, it may be family pathology generally, and not sexual abuse per se, that causes borderline personality disorder. In this case sexual abuse would merely be a noncausal correlate of the true causal factors, which might include, for example, hostility between parents or the lack of appropriate expressions of parental love.

Alternatively, relatives of individuals with borderline personality disorder may be genetically or environmentally predisposed to commit impulsive acts such as sexual abuse. There is evidence that borderline personality traits run in families, though it is currently unclear if this is due to genetic factors (Nigg & Goldsmith, 1994). Regardless, this suggests that the association between childhood sexual abuse and adult borderline personality disorder could reflect the familiality of borderline personality traits rather than a causal association.

Another possibility is that this association is with *reports* of childhood sexual abuse rather than its actual occurrence. Persons with borderline personality disorder are known to be highly manipulative. If they believe they could receive extra sympathy by claiming abuse, they may be inclined to do so whether or not it actually occurred. Finally, borderline personality disorder is often characterized by sexual impulsivity. It is conceivable that even during childhood, individuals who will later be diagnosed with borderline personality disorder behaved in ways that made them more vulnerable to sexual advances of exploitative adults.

The association between childhood sexual abuse and dissociative identity disorder (discussed in Chapter 7) raises an additional alternative hypothesis about causation. This is the possibility that both dissociative identity disorder and (false) memories of childhood sexual abuse can be ***iatrogenic*** (literally, doctor-produced) phenomena, unintentional byproducts of therapy (McHugh, 1993; Spanos, 1994). Highly hypnotizable people are especially likely to produce, under suggestion, a number of responses that resemble symptoms of dissociative identity disorder, including amnesia and the enactment of multiple selves (Spanos, 1994). Indeed, Spanos (1994) has argued that both dissociative identity disorder and hypnotic responding are intentional behaviors aimed at meeting the expectations of experimenters, therapists, or hypnotists. Highly suggestible and hypnotizable people may also be especially likely to produce memories of childhood sexual abuse for therapists who suggest to patients that such abuse is a likely cause of dissociative identity disorder or other problems (McHugh, 1993; Spanos, 1994). The previously mentioned case of Paul Ingram, who came to believe in his own guilt in a number of fantastically lurid sex crimes despite evidence that they never occurred, supports this possibility. Thus, the combination of suggestible patients and overly zealous therapists who "find what they are looking for" may account for the association between memories of sexual abuse and dissociative identity disorder.

We are not asserting that any of these alternatives is more likely than the possibility that sexual abuse causes borderline personality disorder or dissociative identity disorder. Moreover, we do not wish to minimize the pain that true victims of childhood sexual abuse often feel. However, scientific hypotheses succeed by the elimination of plausible rivals. If we wish to understand the consequences of childhood sexual abuse, we shall have to ask, and answer, methodologically and emotionally challenging questions.

Several lines of research may be helpful. For example, prospective studies of sexually abused children could eliminate the possibility that either intentional or unconscious retrospective distortion produced the associations. Similarly, studies following young children could conceivably discern whether certain behavioral tendencies related to adult diagnoses sometimes preceded sexual abuse. Studies of borderline personality disorder patients who were adopted could falsify a genetic hypothesis. If sexual abuse was found to be as common among such patients as among those reared with their biological relatives, this would show that the association was not due to genes causing both borderline personality disorder and sexual abuse. It would also be desirable for theorists to specify more precisely the hypothesized causal mechanisms linking childhood sexual abuse to specific disorders. Why, for instance, should borderline personality disorder be an especially common psychopathological outcome of childhood sexual abuse? If theories become more explicit, they will be easier to test.

Researchers of other disorders have faced similar challenges. For example, depression researchers have had to consider several alternative explanations for the association between depression and memories of recent stress, and they have found that the association is not entirely a causal one (Monroe & Simons, 1991). Research on childhood sexual abuse is still in its infancy, and so it is not surprising that available studies are not yet definitive. Progress will require more sophisticated designs and more attention to alternative hypotheses.

## SUMMARY

Defining boundaries between normality and psychopathology in the area of variant sexuality may be more difficult than for any other topic covered in this book. Sociocultural influences on what have been viewed as normal or aberrant sexual practices abound, giving us reason to pause when we reflect on our own views of what is aberrant. Degeneracy theory and abstinence theory were very influential for long periods of time in the United States and many other Western cultures and led to very conservative views on heterosexual sexuality. The hypothesis that masturbation can cause insanity was also influential for several centuries and appeared in some psychiatry textbooks until the 1940s. In contrast to Western culture, in Melanesia homosexuality is practiced by all adolescent males in the context of male sexual initiation rites. In young adulthood, they make a rather abrupt transition to heterosexuality, in most cases without apparent difficulty. Until rather recently, in many Western cultures homosexuality was viewed as either criminal behavior or as a form of mental illness. However, since 1972 homosexuality is no longer considered by mental health professionals to be abnormal and is considered a normal sexual variant. Currently much research attention is being directed toward understanding the causal factors that determine sexual orientation. The causal factors being explored include a probable genetic component as well as various environmental variables.

Sexual deviations in the form of paraphilias involve persistent patterns of sexual behavior and arousal in which unusual objects or rituals or situations are required for full sexual satisfaction. They almost always occur in males. The paraphilias include: (a) fetishes (in which sexual interest centers on some inanimate object or anatomical part), (b) transvestic fetishism (which involves sexual arousal occurring through cross-dressing behavior), (c) voyeurism (in which sexual pleasure occurs through clandestine peeping), (d) exhibitionism (in which sexual pleasure occurs when the man exposes his genitals to others without their consent), (e) sadism (in which sexual arousal occurs through inflicting cruelty on one's sexual partner), (f) masochism (in which sexual arousal occurs when pain is inflicted on oneself), and (g) pedophilia (in which sexual attraction occurs to prepubescent children). What causes paraphilias is not well understood. One theory is that males are vulnerable to problems in erotic target location. In this view men are not born with an automatic attraction to either women or men but instead must learn which stimuli constitute a female or male sexual partner. Perhaps some men have nervous systems more prone to errors in targeting; this might explain why so many men with paraphilias have more than one.

Gender identity disorders occur in children and adults. Childhood gender identity disorder occurs in children who have cross-gender identification and gender dysphoria. Most boys who have this disorder grow up to have a homosexual sexual orientation; a few become transsexuals. Prospective studies of girls who have this disorder have not yet been reported. Transsexualism is a very rare disorder in which the person believes that he or she is trapped in the body of the wrong sex. It is now recognized that there are two distinct types of transsexuals: homosexual transsexuals (who are attracted to the people of their same biological sex) and nonhomosexual transsexuals (who are attracted to people of the opposite biological sex). The only known effective treatment for transsexuals is a sex change operation. Although its use remains highly controversial, it does appear to have fairly high success rates when the people are carefully diagnosed as being true transsexuals.

There are three overlapping categories of sexual abuse: pedophilia (another form of paraphilia), incest, and rape. All three kinds of sexual abuse occur at alarming rates today, although it is difficult to estimate their true prevalence. There are also many controversies surrounding how perpetrators of any of these categories of sexual abuse are discovered. These include controversies about the accuracy of children's testimony and about the accuracy of recovered memories of sexual abuse that may often occur in psychotherapy. Pedophiles engage in sexual activity with prepubescent children, and quite commonly they are indifferent to the sex of the child. Incest involves sexual molestation of family members; it overlaps with pedophilia when the sexual molestation is of young children. Rape can occur among strangers or among people who know each other, and involves force or threat of force. All sexual abuse can have serious short-term and long-term consequences for its victims. What leads people to engage in sexual abuse is poorly understood at this time. Treatment of sex offenders has not as yet proven highly effective in most cases, although promising research in this area is being conducted.

Sexual dysfunction involves impairment either in the desire for sexual gratification or in the ability to achieve it. There are generally considered to be four phases of the human sexual response: the desire phase, the excitement phase, the orgasm phase, and the resolution phase. Dysfunctions can occur around any of the first three phases. Both men and women can experience hypoactive sexual desire disorder, in which they have little or no interest in sex. In more extreme cases, they may develop sexual aversion disorder, which involves a strong disinclination to sexual activity. Dysfunctions of the arousal phase include male erectile disorder and female arousal disorder. Male erectile disorder can occur for psychological or physiological reasons, or a combination of the two. Dysfunctions of orgasm for men include premature ejaculation and male orgasmic disorder (retarded ejaculation), and for women include female orgasmic disorder. There are also two sexual pain disorders: dyspareunia (painful coitus) which can occur in women and occasionally in men, and vaginismus, which occurs in women. In the past 25 years remarkable progress has been made in treatment of sexual dysfunctions and for some of these dysfunctions the success rates for treatment are quite high.

## KEY TERMS

sexual abuse (p. 399)
paraphilias (p. 404)
fetishism (p. 407)
transvestic fetishism (p. 408)
voyeurism (p. 409)
exhibitionism (p. 410)
sadism (p. 411)
masochism (p. 412)
gender identity disorder (p. 414)
cross-gender identification (p. 414)
gender dysphoria (p. 414)
transsexualism (p. 415)
pedophilia (p. 422)
incest (p. 423)
rape (p. 424)
sexual dysfunction (p. 430)
desire phase (p. 430)
excitement phase (p. 430)
orgasm (p. 431)
resolution (p. 431)
hypoactive sexual desire disorder (p. 431)
sexual aversion disorder (p. 431)
male erectile disorder (p. 432)
female sexual arousal disorder (p. 432)
premature ejaculation (p. 433)
male orgasmic disorder (p. 433)
female orgasmic disorder (p. 434)
vaginismus (p. 434)
dyspareunia (p. 434)

UNRESOLVED ISSUES ON SCHIZOPHRENIA

SUMMARY

KEY TERMS

With the schizophrenias, we move into a realm of disorder that represents in many ways the ultimate in psychological breakdown. These disorders include some of the most extreme of human behaviors, the ultimate in **psychosis,** a term referring to pervasive loss of contact with reality. The hallmark of **the schizophrenias** is thus a more or less sharp break with the world in which most less disturbed people live, a world that is rooted in a basic consensus about what is true and real in our shared experience. The typical schizophrenic person is thus someone who has lost or become detached from a set of anchoring points fundamental to adequate integration and communication with the surrounding human environment. To those around the schizophrenic he or she appears incomprehensible, perhaps even frightening.

If we look more closely, trying to identify the component processes underlying this detachment from reality, we observe in schizophrenics many psychological abnormalities. These include peculiarities in action, thinking, perception, feeling, sense of self, and manner of relating to others, with the features displayed varying from one patient to another. As is implied here, the group is a heterogeneous one, and this heterogeneity extends well beyond differences in current behavior. As we shall see, it includes as well marked variations in associated background features, in the course of the disorder in different people, and in the variety of outcomes they experience.

In the face of this heterogeneity, many clinicians and researchers have concluded that "schizophrenia" will probably someday be recognized as consisting of several separate and distinct conditions. We share that expectation, which explains our choice of the plural form in the title of this chapter.

As that title also indicates, we will in addition consider in this chapter the condition the DSM-IV calls ***delusional disorder,*** whose main features were formerly included under the classic rubric ***paranoia,*** or ***"true" paranoia*** (to distinguish it from the paranoid subtype of schizophrenia, described below). Patients with delusional disorders, like many schizophrenics, nurture, give voice to, and sometimes take actions based on, beliefs that are considered completely false and absurd by those around them. Unlike schizophrenics, however, persons with delusional disorders may otherwise behave quite normally. Their behavior does not show the gross disorganization and fragmentation characteristic of schizophrenia, and general behavioral deterioration is rarely observed in this disorder even when it proves chronic.

## THE SCHIZOPHRENIAS

The disorders now called schizophrenia were at one time attributed to a type of mental deterioration beginning early in life. In 1860 the Belgian psychiatrist Benedict Morel described the case of a 13-year-old boy who had formerly been the most brilliant pupil in his school but who gradually lost interest in his studies, became increasingly withdrawn, lethargic, seclusive, and quiet, and appeared to have forgotten everything he had learned. He talked frequently of killing his father. Morel thought the boy's intellectual, moral, and physical functions had deteriorated as a result of brain degeneration of hereditary origin, and hence were irrecoverable. He used the term ***démence précoce*** (mental deterioration at an early age) to describe the condition and to distinguish it from the dementing disorders associated with old age.

The Latin form of this term—***dementia praecox***—was subsequently adopted by the German psychiatrist Emil Kraepelin to refer to a group of conditions that all seemed to have the feature of mental deterioration beginning early in life. Actually, however, the term is somewhat misleading, because there is no persuasive evidence of progressive (i.e., worsening over time) brain degeneration in the natural course of most instances of the disorder (Bogerts, 1993; Heaton et al., 1994).

It remained for a Swiss psychiatrist, Eugen Bleuler, to introduce in 1911 a more acceptable descriptive term for this general class of disorders. He used ***schizophrenia*** (split mind) because he thought the condition was characterized primarily by disorganization of thought processes, a lack of coherence between thought and emotion, and an inward orientation away (split off) from reality. The "splitting" thus does *not* refer to multiple personalities, an entirely different form of disorder discussed in Chapter 7 (and now called "dissociative identity disorder"). Instead, in schizophrenia there is a split within the intellect, between the intellect and emotion, and between the intellect and external reality. The subtitle of Bleuler's monograph on the subject (Bleuler, 1911/1950) was *The Group of Schizophrenias,* indicating his own belief in multiple forms in which this basic psychic splitting might be manifested.

Schizophrenic disorders seem to occur in virtually all societies, from the aboriginal settlements in the western Australian desert to the remote interior jungles of Malaysia to the most technologically advanced societies. However, incidence/prevalence rates for the schizophrenias are difficult to pin down precisely because of variations over time and place in the criteria for defining cases. Overall lifetime prevalence estimates have ranged from approximately 0.2 to 2.0 percent (American Psychiatric Association, 1994). The one-year prevalence rate for schizophrenia in the United States among persons 18 or older is estimated at 1.1 percent, or approximately two million affected persons (Regier et al., 1993). Because these disorders are frequently chronic, their incidence (occurrence or onset rate) would be expected to be considerably lower and is estimated in the DSM-IV manual (APA, 1994) as 1 per 10,000 persons per year. Detailed analysis of Epidemiologic Catchment Area (described in Chapter 1) data suggest that the latter rate seriously underestimates occurrence in the United States. Tien and Eaton (1992) estimate the U.S. cumulative occurrence rate at 2 per 1000 persons per year.

In recent years schizophrenia has been the primary diagnosis for nearly 40 percent of all admissions to state and county mental hospitals, far outstripping all other diagnostic categories; it has been the second most frequent primary diagnosis (the first being either mood or alcohol-related disorders) for every other type of inpatient psychiatric admission, including private hospitals (Manderscheid et al., 1985). Forty-five percent of schizophrenic persons receiving hospital care during a given year receive that care in state and county mental hospitals, a proportion exceeded only by patients with severe cognitive impairment (e.g., Alzheimer's dementia). During any given recent year more than 1 million people in the United States received outpatient care for a primary diagnosis of schizophrenia (Narrow et al., 1993). Because schizophrenic persons often require prolonged or repeated hospitalization, they have historically occupied about half of all available mental hospital beds in this country.

Although schizophrenic disorders sometimes first occur during childhood or old age, about three-fourths of all initial onsets occur between the ages of 15 and 45, with a median age in the mid-20s. The incidence rate, overall, appears to be about the same for males and females, but males tend to have earlier onsets (early to mid-20s versus late 20s for females), and many researchers believe males develop more severe forms of these disorders (Iacono & Beiser, 1992; Marcus et al., 1993; Tien & Eaton, 1992). The schizophrenias, because of their complexity, their high rate of incidence (especially at the beginning of adult life), and their tendency to recur or become chronic, are considered the most serious of all mental disorders, as well as among the most baffling.

## A Case Study

We depart somewhat from our usual format in discussing the clinical syndromes to present first a unique and uniquely well-documented case study of schizophrenia. The case involves a family of six—two biological parents and their four monozygotic, quadruplet daughters—in which all four daughters became schizophrenic before age 25. Some appreciation of just how remarkable this circumstance is can be derived from the combined improbability of viable quadruplet births, identical heredity, and perfect concordance for schizophrenia; a fairly liberal estimate is that it would occur once in every 1.5 billion births. We are indebted for the thorough knowledge we have of this family to David Rosenthal (1963) and his colleagues, working under the auspices of the National Institute of Mental Health. For obvious reasons, certain specific but nonessential data, such as names and dates, have been omitted or altered in the report.

**Background and Early Years** Some time in the early 1930s, quadruplet girls were born to Mr. and Mrs. Henry Genain, the product of a marriage occasioned by Mr. Genain's threatening to kill the reluctant Mrs. Genain unless she consented to it. Except for their low birth weights, ranging from Nora's 4 lb, 8 oz., to Hester's 3 lb, the girls appeared to be reasonably normal babies, albeit premature. Hester had to be fitted with a truss (an abdominal compression device) because of a hernia but was nevertheless discharged from the hospital with her sisters as basically healthy some six weeks after the birth.

From birth, the girls received a great deal of attention from the media and the public. Early on, in fact, their parents started charging public admission to visit the home and view the babies, an enterprise that ended when the parents became concerned about the possibility of kidnapping or the transmission of some disease to the children. In subsequent years the children were encouraged in dancing and singing as a team, and they performed often at various functions. Partly as a result of their celebrity status, the girls tended to stick closely together for mutual protection; they even rebuffed children their own age, with the result that they became social isolates. They were encouraged in this social isolation by their parents, who shared strong anxieties about the dangers of "the outside world."

Notwithstanding their genetic identity and physical similarity, the girls were sharply differentiated by their parents. They were treated as though they were two sets of twins—a superior and talented set consisting of Nora and Myra, and an inferior, problematic set consisting of Iris and Hester. Hester—the "runt of the litter"—was regarded from an early age as oversexed. (Possibly because of irritation from her truss, Hester began to masturbate regularly by the age of three, a habit she continued for many years to the dismay of her parents.) Complying with parental attributions, the girls did in fact pair up for purposes of mutual support and intimacy; when threatened from the outside, however, they became a true foursome.

Mr. Genain's job was not very demanding, and he spent most of his time drinking and expressing his various fears and obsessions to his family. Prominent among these were fears that break-ins would occur at the home unless he patrolled the premises constantly with a loaded gun, and, especially as the girls developed into adolescence, that they would get into sexual trouble or be raped unless he watched over them with total dedication.

He imposed extreme restrictions and surveillance on the girls until the time of their breakdowns. Beginning at an early age and persisting through early adulthood, Mr. Genain insisted on being present when his daughters dressed and undressed. He even insisted on watching them change their sanitary pads during menstruation. He was himself sexually promiscuous and was reported to have sexually molested at least two of his daughters; possibly Myra, who persistently distanced herself from him, was the only one of the girls not to be molested.

Mr. Genain's preoccupation with sexuality, while extreme, was matched by that of his wife. Mrs. Genain managed to see sexuality and sexual threats in the most innocuous circumstances and yet seemingly ignored real sexual activity occurring in the home. When the girls complained to her about Mr. Genain's sexual approaches, she rationalized that Mr. Genain was merely testing their virtue; if they objected to his advances, then clearly all was well. Not that she saw Mr. Genain as a paragon of virtue; on the contrary, she recited his many faults to anyone who would listen. Nevertheless, she stuck by him to the end (a typically alcoholic end) and largely confirmed and supported his bizarre constructions of reality. Hester, the chronic masturbator, was a particular thorn in her side—all the more so when she discovered that, at about age 12, Hester had apparently introduced Iris to the practice of mutual masturbation, which Iris found pleasing. Apparently unable to think of any more appropriate response to this dilemma, the parents—on the questionable advice of a physician—forced the two girls to submit to clitoral circumcisions, a drastic measure that failed to alter their behavior. In general, however, Mrs. Genain enjoyed the status accorded her as the mother of quadruplets, and she remained unfailingly and overwhelmingly involved in the girls' lives. Most of her affection was reserved for the "good" quads, Nora and Myra.

**Adolescence, Young Adulthood, and Breakdown** Except for their social isolation, the girls had a relatively uneventful junior high school and high school experience. They were regarded by their teachers as conforming, hard-working, and "nice," except for some competition among them with respect to grades and adult approval. Hester lagged behind the others, and Iris could not quite keep up with the remaining two in academic performance. In the summer before the girls' senior year, Hester, whose behavior had become peculiar and who was suffering from some type of psychogenic gastrointestinal distress, finally became disturbed to the point that her parents could hardly manage her. She was temperamental, often confused, destroyed household furnishings, tore both her own and her sisters' clothing, and on one occasion struck Nora and knocked her unconscious. Hester had just turned 18; she never recovered effective mental functioning.

The other three girls completed their senior year of high school. Outwardly they appeared to be normal adolescents, although they were not permitted to have boyfriends and continued to have physical difficulties, including menstrual irregularities and persistent enuresis (bed-wetting). Following graduation, they obtained employment as office workers. They continued to be spied on by their father, however, lest they become involved in sexual liaisons. Of the three, Myra maintained the most independence, defying her father's edict that she not go out at night.

None of the three young women was comfortable in the world of work. Nora was the first to evidence unusual "nervousness," and at age 20 began to have a series of vague physical complaints. She eventually quit her job and took to her bed at home, gradually becoming more disturbed. She stood on her knees and elbows until they became irritated and bled, and began to walk and talk in her sleep. Her behavior continued to deteriorate until, at age 22, she was admitted to a hospital with the diagnosis of schizophrenia. In the meantime, Iris had also become increasingly disturbed, and resigned from her job. She was troubled by "spastic colon," vomiting, insomnia, and the belief that people were paying her undue attention. In fact it was later learned that Mr. Genain may have been molesting her at the time. Within several months after Nora's first admission, Iris "just went to pieces." She screamed, was markedly agitated, complained of hearing voices and of people fighting, and drooled at meals, being unable to swallow anything but liquids. She, too, was hospitalized toward the end of her twenty-second year. The diagnosis was schizophrenia.

Myra did not break down until age 24. The onset was similar to that of her sisters. Myra resisted hospitalization and was not hospitalized until the entire family was shortly thereafter moved to the Clinical Center of the National Institute of Mental Health (NIMH). There, as a unit, they underwent the lengthy and detailed study of which this history is one product. On arrival, Myra was autistic, disordered in thought, and impaired in judgment and reality testing. She was diagnosed as schizophrenic. It may be significant that in the cases of Nora, Iris, and Myra, deterioration began shortly after an incident in which a man had made rather insistent "improper advances."

**Course and Outcome** By the time they arrived at the Clinical Center at age 24, Nora had undergone

*In 1981 the Genains performed a rendition of "Alice Blue Gown" at a birthday party held in their honor at the National Institute of Mental Health.*

three separate hospital admissions and Iris five. Hester had somehow escaped hospitalization, although she was often bizarre and psychotic at home.

Once at the NIMH, the sisters were offered varied forms of treatment and care, including the new antipsychotic medications that had recently become available. They remained at the NIMH for three years. At the end of their stay, Myra was the only one capable of attaining a sustainable discharge. The other three sisters were transferred to a state hospital. Mr. Genain had died of liver disease in the interim.

It is important to note that, though the earliest symptoms of the quads were similar in certain respects, the courses and outcomes of their disorders differed markedly and, to some extent, in ways that might have been predicted from manifestations that appeared quite early. The behavior of Hester and Iris, as described in hospital records, was persistently deteriorated. By contrast, Nora and Myra did not evidence the marked behavioral disorganization of their less functional sisters, although Myra's behavior was the more consistently appropriate over time. The quads' outcomes show a corresponding pattern. At the time of Rosenthal's 1963 report, Myra was working steadily, married, and doing well. Nora was making a marginal adjustment outside the hospital. Iris was still fluctuating between periods of severe disturbance and relative lucidity in which she could manage brief stays outside of the hospital. Hester remained continuously hospitalized in a condition of severe psychosis and was considered essentially a "hopeless case."

It is a tribute to the scientific diligence of the NIMH staff and to David Rosenthal, who maintained both a human and a scientific interest in this unfortunate family, that we had a follow-up report some 20 years after the original one (DeLisi et al., 1984; Mirsky et al., 1984; Sargent, 1982a). In general, the relative adjustment of the sisters, then in their 50s, remained in 1982 as it had been in the 1960s. Myra continued to do well and had had two children in the interim. The other three women were living at home with their mother, with Nora continuing to show a higher level of functioning than Iris or Hester. All of the quads were on continuous medication, and even the beleaguered Hester appeared to have overcome to an extent her originally dismal prognosis. It is of considerable interest that newer techniques of neurological assessment showed that Nora had impairments of the central nervous system similar to those of Hester, and yet her outcome seemed far better than that of Hester or even Iris. It is possible that the original pairing of Iris with Hester was inappropriate (at least in the limited sense implied here) and destructive of Iris's development. In any event, we see that the quads, despite their identical heredity, array themselves along a considerable range of the possible outcomes associated with schizophrenic breakdown.

**Interpretive Comment** We have here, then, four genetically identical women, all of whom experienced schizophrenic disorders. The disorders, however, have been different in severity, chronicity, and eventual outcome. Obviously these differences must be ascribed to differences in the environments the quads experienced, including their intrauterine environments, which presumably contributed to their modest variations detectable at birth. Clearly Hester, possibly most compromised biologically and in relative parental disfavor from the beginning, faced the harshest environmental conditions, followed closely by her "twin," Iris. The outcome for these women has been grim. Myra was the most favored youngster and the one who experienced the least objectionable parental attention, partly owing to a greater independence and assertiveness than her sisters displayed. Nora was a close second in this respect but had the misfortune of being her incestuous father's "favorite"; in recent tests, she was also shown to have a compromised central nervous system (specifically, an imbalance of metabolic rates in different brain areas) comparable to that of Hester. Though Nora has not done as well as Myra, she has emerged as clearly superior in functioning to the other two sisters. We see here the considerable power of environmental forces in determining personal destiny, even in schizophrenia.

But let us look again. We have four genetically identical women, all of whom became schizophrenic within a period of six years—three of them within a period of some two years. Is this not a compelling case for genetic determination? An independent genealogical history suggests that the quads' father may have harbored some pathogenic genes, which could have been passed on to his daughters. On the other hand, we also see a far less-than-ideal environmental context for the girls' development. As Rosenthal (1963) pointed out, their parents failed spectacularly in the most elementary tasks of parenthood. Assuming the quads were at a genetically enhanced risk for schizophrenia, might they have been spared this outcome had their development occurred in a more psychosocially favorable climate? Unfortunately, there is no way to answer this question.

A plausible conclusion is that both heredity and environment, operating in an as yet poorly understood interaction, probably determined the Genain sisters' psychotic outcomes. To put it another way, it appears we are confronted here with a striking example of the diathesis-stress model of etiology (see Zubin & Spring, 1977), outlined in Chapter 3. We will encounter this type of complicated causal scenario repeatedly in the pages to follow.

## The Clinical Picture in Schizophrenia

Sometimes schizophrenic disorders develop slowly and insidiously. In such cases a person may become seclusive, gradually seem to lose interest in the surrounding world, to spend much time daydreaming, to lose emotional responsivity, and to behave socially in mildly inappropriate ways, such as grimacing peculiarly or failing to appreciate social proprieties. This pattern of symptoms has traditionally been referred to as **process schizophrenia**—that is, it develops gradually over a period of time, not in response to obvious discrete stressors, and tends to be long-lasting. The outcome for process schizophrenia is considered generally unfavorable, partly perhaps because the need for treatment is usually not recognized until the behavior pattern has become firmly entrenched. *Poor premorbid* (referring to personality features existing before the occurrence of actual disorder) or *chronic* schizophrenia are alternative terms referring to this pattern.

In other cases, the onset of schizophrenic symptoms is sudden and dramatic and is marked by intense emotional turmoil and a nightmarish sense of confusion. This pattern, which is often associated with identifiable precipitating stressors, is referred to as **reactive schizophrenia** (alternatively, *good premorbid* or *acute* schizophrenia). Here the symptoms may clear up in a matter of weeks, though in some cases an acute episode is the prelude to a more chronic pattern.

Today the terms **negative-symptom schizophrenia** and **positive-symptom schizophrenia** are used to refer to two symptom patterns that appear to overlap considerably with the older process and reactive designations, respectively (Andreasen, 1985). While there is not complete agreement about what types of symptoms should be considered "negative" (Andreasen, 1985; McGlashan & Fenton, 1992; Raskin et al., 1993), the term refers to an *absence* or *deficit* of behaviors normally present in a person's repertoire, such as emotional expression, communicative speech, or reactivity to the environment. *Positive* symptoms, by contrast, are those in which something has been *added* to a normal repertoire of behavior and experience, such as marked emotional turmoil, motor agitation, delusional interpretation of events, or hallucinations. Although most patients exhibit both positive and negative symptoms during the course of their disorders, a preponderance of negative symptoms has increasingly been shown to have relatively grave prognostic significance (e.g., Fenton & McGlashan, 1994; McGlashan & Fenton, 1993).

It is sometimes held that antipsychotic medication affects only positive symptoms. This appears to be an incorrect clinical observation, however, since it has been known for many years that negative symptoms, such as social withdrawal, may also respond to these medications (NIMH Psychopharmacology Service Center Collaborative Study Group, 1964). This finding was reconfirmed by Kay and Singh (1989) and by Breier and colleagues (1994) in more rigorously designed studies. Another widespread belief, already mentioned, is that positive schizophrenia has a better long-term prognosis than negative schizophrenia, but the 36-month follow-up of their patients by Kay and Singh surprisingly found the opposite. Since there is growing evidence (e.g., Fenton & McGlashan, 1994) indicating that the latter finding is anomalous, we suspect that the difficulty here relates to uncertainty in the identification of positive versus negative symptoms.

One source of this uncertainty is undoubtedly the tendency to consider the positivity/negativity distinction to be dichotomous. In fact, it is not a dichotomy, nor even necessarily a single dimension. Research evidence indicates that these polar terms would better be conceived as the end points of an uninterrupted continuum, or possibly two separate and largely independent continua. Instances of schizophrenic disorder can be seen as distributing themselves in the familiar bell-shaped curve, with relatively few falling at either the negative- or positive-symptom extremes and most falling somewhere in the middle. We thus expect a large percentage of schizophrenic patients to display both positive and negative symptoms, as seems to be the case (Breier et al., 1994; Guelfi, Faustman, & Csernansky, 1989). Everything considered, therefore, we remain somewhat doubtful that the distinction now designated by the positive/negative rubric will prove to be basic to the organization of schizophrenic psychopathology. Similar reservations have been expressed by Andreasen and colleagues (1990) following a more comprehensive review of the evidence.

Another distinction commonly emphasized by researchers is that between paranoid and nonparanoid symptom patterns in schizophrenia. The paranoid is

*Odd behavior and active withdrawal from the social environment are frequently observed phenomena in schizophrenia.*

one of the classical subtypes of schizophrenia, of which more is said below. In the paranoid pattern, delusions, particularly organized persecutory or grandiose ones, are a dominant feature; in the nonparanoid forms, delusions, if present at all, tend to be incidental to a generalized confusion and of inconsistent content. There is considerable evidence that important differences exist between those who exhibit a predominantly paranoid symptom pattern and those who exhibit few, or no, or inconsistent paranoid symptoms.

In general, paranoid schizophrenics tend to be more reactive than process in type and to have more benign courses and outcomes (Kendler et al., 1994b; Ritzler, 1981); they are less likely to show the striking kinds of cognitive or attentional deficits seen in other forms of the disorder (Rabin, Doneson, & Jentons, 1979). They may also be genetically less vulnerable to schizophrenia than nonparanoid types (Kendler & Davis, 1981). It has been found, however, that a substantial number of people originally diagnosed as having paranoid forms of schizophrenic disorder are later diagnosed as having nonparanoid ones (Kendler & Tsuang, 1981). Also, there appears to be a small subgroup of paranoid schizophrenic people whose disorders are extremely intractable and chronic.

Whether positive, negative, paranoid, or nonparanoid in the general sense of these terms, schizophrenia encompasses many specific symptoms that vary greatly over time in an individual's life and from one person to another, perhaps especially with respect to the emergence or progression of negative symptoms (McGlashan & Fenton, 1993). The basic experience in schizophrenia, however, seems to be disorganization in perception, thought, and emotion to the extent that the affected person is no longer able to perform customary social roles in an adequate fashion. The DSM-IV specifies in concrete terms a list of criteria for the diagnosis, reproduced in HIGHLIGHT 12.1. What follows is a more elaborated version of the schizophrenia construct as it has evolved to this point.

### Disturbance of Language and Communication

First described at length by Bleuler (1911/1950) and often referred to as *formal thought disorder,* communication disturbance is usually considered a prime indicator of a schizophrenic disorder. Basically, an affected person fails to make sense, despite seeming to conform to the semantic and syntactic rules governing verbal communication. The failure is not attributable to low intelligence, poor education, or cultural deprivation. Meehl (1962) aptly referred to the process as one of "cognitive slippage"; others have referred to it as "derailment" or "loosening" of associations. However labeled, the phenomenon is readily recognized by experienced clinicians: The patient seems to be using words in combinations that sound communicative, but the listener can understand little or nothing of what is said. As an example from the files of one of the authors, consider the following excerpt from a letter addressed to Queen Beatrix of the Netherlands by a highly intelligent schizophrenic man:

12.1

## DSM-IV Criteria for the Diagnosis of Schizophrenia

A. *Characteristic symptoms:* Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):

(1) delusions
(2) hallucinations
(3) disorganized speech (e.g., frequent derailment or incoherence)
(4) grossly disorganized or catatonic behavior
(5) negative symptoms, i.e., affective flattening, alogia [little speech, or little substance of ideas contained in speech], or avolition [deficient or absence of "will"]

**Note:** Only one Criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices conversing with each other.

B. *Social/occupational dysfunction:* For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

C. *Duration:* Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodomal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. *Schizoaffective and Mood Disorder exclusion:* Schizoaffective Disorder and Mood Disorder With Psychotic Features have been ruled out because either (1) no Major Depressive, Manic, or Mixed Episodes have occurred concurrently with active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

E. *Substance/general medical condition exclusion:* The disturbance is not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

F. *Relationship to a Pervasive Developmental Disorder:* If there is a history of Autistic Disorder or another Pervasive Developmental Disorder, the additional diagnosis of Schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

American Psychiatric Association, 1994, pp. 285–86.

> I have also "killed" my ex-wife, [name], in a 2.5 to 3.0 hours sex bout in Devon Pennsylvania in 1976, while two Pitcairns were residing in my next room closet, hearing the event. Enclosed, please find my urology report, indicating that my male genitals, specifically my penis, are within normal size and that I'm capable of normal intercourse with any woman, signed by Dr. [name], a urologist and surgeon who performed a circumcision on me in 1982. *Conclusion:* I cannot be a nincompoop in a physical sense (unless Society would feed me chemicals for my picture in the nincompoop book).

**Disturbance of Thought Content** Disturbances in the content of thought typically involve certain standard types of **delusion** (false belief). Prominent among these are beliefs that one's thoughts, feelings, or actions are being controlled by external agents; that one's private thoughts are being broadcast indiscriminately to others; that thoughts are being inserted into one's brain by alien forces; that some mysterious agency has robbed one of one's thoughts; or that some neutral environmental event (such as a television program or a billboard) has an intended personal meaning, often termed an "idea of reference." Other absurd propositions, including delusions of grotesque bodily changes, are regularly observed.

**Disruption of Perception** Major perceptual disruption often accompanies the criteria already indicated. The patient seems unable to sort out and process the great mass of sensory information to which all of us are constantly exposed. As a result, stimuli overwhelm the meager resources the person has for information processing. This point is illustrated in the following statements of schizophrenic people: "I feel like I'm too alert . . . everything seems to come pouring in at once . . . I can't seem to keep anything out. . . ." "My nerves seem supersensitive . . . objects seem brighter . . . noises are louder . . . my feelings are so intense . . . things seem so vivid and they come at me like a flood from a broken dam." "It seems like nothing ever stops. Thoughts just keep coming in and racing round in my head . . . and getting broken up . . . sort of into pieces of thoughts and images . . . like tearing up a picture. And everything is out of control . . . I can't seem to stop it." It is estimated that approximately 50 percent of patients diagnosed as schizophrenic experience this breakdown of perceptual selectivity during the onset of their disorders (Freedman & Chapman, 1973). Other even more dramatic perceptual phenomena include **hallucinations**—false perceptions, such as "voices" that only the schizophrenic person can hear. Hallucinations in the schizophrenias are most often auditory, although they can also be visual and even olfactory. The typical hallucination is one in which a voice (or voices) keeps up a running commentary on the person's behaviors or thoughts.

**Inappropriate Emotion** The schizophrenic syndromes are often said to include an element of clearly inappropriate emotion, or affect. In the more severe or chronic cases, the picture is usually one of apparent anhedonia (inability to experience joy or pleasure) and emotional shallowness or "blunting" (lack of intensity or clear definition). The person may appear virtually emotionless, so that even the most compelling and dramatic events produce at most an intellectual recognition of what is happening. We must be cautious in interpreting this sign, however, because evidence suggests that the deficit is only one of expressiveness, not of feeling per se (Berenbaum & Oltmanns, 1992; Kring et al., 1993). In other instances, particularly in the acute phases, the person may show strong affect, but the emotion clashes with the situation or with the content of his or her thoughts.

**Confused Sense of Self** Schizophrenic persons may feel confused about their identity to the point of loss of a subjective sense of self or of personal agency. Delusional assumption of a new identity is not uncommon. In other instances the person may be perplexed about aspects of his or her own body, including its gender, or may be uncertain about the boundaries separating the self from the rest of the world. The latter confusion is often associated with frightening "cosmic" or "oceanic" feelings of being somehow intimately tied up with universal powers, including the deity. These feelings appear to be related to ideas of external control and similar delusions.

**Disrupted Volition** Goal-directed activity is almost universally disrupted in schizophrenic individuals. The impairment always occurs in areas of routine daily functioning, such as work, social relations, and self-care, such that observers note that the person is not himself or herself any more. The picture is thus one of deterioration from a previously mastered standard of performance in everyday affairs. For example, the person may no longer maintain minimal standards of personal hygiene, or may evidence a profound disregard of personal safety and health.

**Retreat to an Inner World** Ties to the external world are almost by definition loosened in the schizophrenic disorders. In extreme instances the withdrawal from reality seems deliberate and involves active disengagement from the environment. This rejection of the external world may be accompanied by the elaboration of an inner world in which the person develops illogical and fantastic ideas, including the creation of strange beings who interact with the person in various self-directed dramas. Since the days of Bleuler, this process has generally been referred to as *autism*.

**Disturbed Motor Behavior** Various peculiarities of movement are sometimes observed in the schizophrenias; indeed, this is the chief and defining characteristic of catatonic schizophrenia, of which more will be said later. These motor disturbances range from an excited sort of hyperactivity to a marked decrease in all movement or an apparent clumsiness. Also included here are various forms of rigid posturing, mutism, ritualistic mannerisms, and bizarre grimacing.

## Problems in Defining Schizophrenia

Criteria for the diagnosis of schizophrenia have varied considerably over the past century (Hegarty et al., 1994). In an effort to provide for a clear-cut diagnosis of schizophrenia and to sharply distinguish it from mood or other disorders, diagnostic criteria since the DSM-III of 1980 have been far more exact and explicit than those in earlier DSM editions. Recalling our discussion of these matters in Chapter 1, such an approach almost necessarily enhances diagnostic reliability (that is, the agreement on what diagnosis should be assigned). Whether it does the same for validity (the conceptual and predictive meaningfulness of the diagnosis) depends on the adequacy with which the category, so defined, captures some essential truth about a distinctive psychopathological entity that is to be called *schizophrenia*. While no reasonable person doubts the reality of the behavioral phenomena described above, it has proven difficult to identify or to formulate in exact terms the central nature of this presumed entity.

Despite the dramatic quality of the associated clinical phenomena, therefore, it must be kept in mind that schizophrenia remains a *provisional construct* (Andreasen & Carpenter, 1993), one whose definition has evolved and changed over time—with substantial effects on incidence/prevalence rates relative to other disorders (Carson & Sanislow, 1993), and even on observed clinical outcomes for persons assigned the diagnosis (Hegarty et al., 1994). Criteria for applying the diagnosis may change with future changes in conceptualization, as they have in each of the three most recent editions of the DSM since 1980.

In pointing out the changing empirical foundations for the construct of schizophrenia, we are not suggesting that it should be abandoned—still less that we can offer a superior alternative solution to the continuing conceptual confusion attending this type of disorder. Consensus on the definition of a disorder, and hence reliability in diagnosing it, are after all essential to the conduct of relevant research. Our intent is to ensure that the student avoid the common error of attributing to the provisional construct of "schizophrenia" a substantive existence—a reification—that available evidence cannot support. There is clearly *something* decidedly wrong, quite apart from mere violation of convention, with the mental functioning of the persons who acquire this diagnosis (Keith, 1993). Unfortunately, however, accurate diagnosis in itself does not at present provide us with any confident understanding of what that underlying "something" may be.

## Subtypes of Schizophrenia

Recent editions of the DSM have listed five subtypes of schizophrenia, based on the differing clinical pictures long recognized to be variants of a common theme of disorder; they are summarized in HIGHLIGHT 12.2. We will focus on four of these here: undifferentiated, catatonic, disorganized, and paranoid. Of these, the undifferentiated and paranoid types are the most common today.

**Undifferentiated Type** As the term implies, the diagnosis of **schizophrenia, undifferentiated type,** is something of a "wastebasket" category. A person so diagnosed meets the usual criteria for schizophrenia—including (in varying combinations) delusions, hallucinations, disordered thoughts, and bizarre behaviors—but does not clearly fit into one of the other types because of a mixed symptom picture. People in the acute, early phases of a schizophrenic breakdown frequently exhibit undifferentiated symptoms, as do those who are in transitional phases from one to another of the standard subtypes.

Probably most instances of acute, reactive schizophrenic breakdown occurring for the first time appear undifferentiated in type. However, current diagnostic criteria (that is, DSM-IV) preclude the diagnosis of schizophrenia unless there have been signs of the disorder for at least six months, by which time a stable pattern may develop, consistent with a more definite indication of type. Some schizophrenic patients, on the other hand, remain undifferentiated over long time periods. The case of Rick Wheeler is illustrative of the latter course:

> Rick Wheeler, 26 years old, neatly groomed, and friendly and cheerful in disposition, was removed from an airplane by airport police because he was creating a disturbance—from his own account probably because he was "on another dimension." On arrest, he was oriented to the extent of knowing where he was, his name, and the current date, but his report of these facts was embedded in a peculiar and circumstantial context involving science fiction themes. Investigation revealed he had been discharged from a nearby state mental hospital three days earlier. He was brought to another hospital by police.
>
> On admission, physical examination and laboratory studies were normal, but Rick claimed he was Jesus Christ and that he could move mountains. His speech was extremely difficult to follow because of incoherence and derailment. For example, he explained his wish to leave the city, "because things happen here I don't approve of. I approve of other things but I don't approve of the other things. And believe me it's worse for them in the end." He complained that the Devil wanted to kill him and that his food contained "ground-up corpses." He was born, he claimed, from his father's sexual organs.
>
> Background investigation revealed that Rick's difficulties began, after a successful academic start, in elementary school: "I could compre-

12.2

## Types of Schizophrenia

| Type | Characteristics |
|---|---|
| **Undifferentiated type** | A pattern of symptoms in which there is a rapidly changing mixture of all or most of the primary indicators of schizophrenia. Commonly observed are indications of perplexity, confusion, emotional turmoil, delusions of reference, excitement, dreamlike autism, depression, and fear. Most often this picture is seen in patients who are in the process of breaking down and becoming schizophrenic. It is also seen, however, when major changes are occurring in the adjustive demands impinging on a person with an already-established schizophrenic psychosis. In such cases, it frequently foreshadows an impending change to another primary schizophrenic subtype. |
| **Paranoid type** | A symptom picture dominated by absurd, illogical, and changeable delusions, frequently accompanied by vivid hallucinations, with a resulting impairment of critical judgment and erratic, unpredictable, and occasionally dangerous behavior. In chronic cases, there is usually less disorganization of behavior than in other types of schizophrenia, and less extreme withdrawal from social interaction. |
| **Catatonic type** | Often characterized by alternating periods of extreme withdrawal and extreme excitement, although in some cases one or the other reaction predominates. In the withdrawal reaction there is a sudden loss of all animation and a tendency to remain motionless for hours or even days in a single position. The clinical picture may undergo an abrupt change, with excitement coming on suddenly, wherein an individual may talk or shout incoherently, pace rapidly, and engage in uninhibited, impulsive, and frenzied behavior. In this state, an individual may be dangerous. |
| **Disorganized type** | Usually occurs at an earlier age than most other types of schizophrenia, and represents a more severe disintegration of the personality. Emotional distortion and blunting typically are manifested in inappropriate laughter and silliness, peculiar mannerisms, and bizarre, often obscene, behavior. |
| **Residual type** | Mild indications of schizophrenia shown by individuals in remission following a schizophrenic episode. |

hend but I couldn't store . . . it's like looking at something but being unable to take it in." He thereafter maintained a D average until he dropped out halfway through his junior year of high school. He had never held a full-time job, and his social adjustment had always been poor. He showed no interest in women until he married, at age 19, a patient he'd met during one of the earliest of some 20 of his hospitalizations, beginning at age 16. A daughter was born from this match, but Rick had lost track of both her and his wife; he had shown no further interest in women. Rick himself was the eldest of five children; there was no known mental disorder in any of his first-degree relatives (that is, siblings and parents).

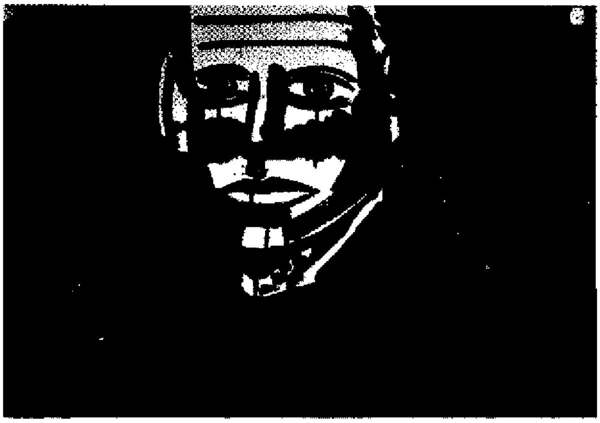
Unable to maintain employment, Rick had been supported mainly on federal disability welfare—and by virtue of patienthood in public hospitals. His hospital admissions and discharges showed a substantial correlation with his varying financial status; that is, he tended to be released from the hospital around the first of the month, when his welfare check was due, and to be readmitted (or alternatively sent to jail) following some public altercation after his money had run out. Numerous attempts to commit Rick to the hospital indefinitely on an involuntary basis had failed because he was able to appear competent at court appearances. He had, however, been declared incompetent to receive his own checks, and various relatives had stepped forward to handle his finances. Now they are afraid to do so because Rick set his grandmother's house afire, having concluded (erroneously, as it turned out) that she was withholding some of his money. He had also threatened others and had been arrested several times for carrying concealed weapons.

In the latest hospitalization, two different antipsychotic medications were tried over a period of five weeks with no discernible improvement. Rick still claimed supernatural powers and special connections with several national governments; was still refusing food because of its contamination with ground corpses; and was still threatening bodily harm to people he found uncooperative. A further attempt was made to commit him and to place his affairs under legal guardianship. As Rick had rather boastfully predicted, this attempt failed because of his lucid defense of himself, and the court dismissed the action. He was discharged to a protected boarding house but disappeared four days later. (Adapted from Spitzer et al., 1983, pp. 153–155)

Fortunately, most patients who show this type of chaotic, undifferentiated pattern do not have the early and slowly developing, insidious onset seen in Rick's case. On the contrary, the breakdown erupts suddenly out of the context of a seemingly unremarkable life history, usually following a period of stress. The initial diagnosis in such cases is *schizophreniform disorder* (see below), and the episode usually clears up in a matter of weeks or, at most, months. Recurrent episodes, however, are not uncommon in schizophreniform disorder, especially in the absence of vigorous follow-up treatment, leading to the diagnosis of schizophrenia. In some few instances, treatment efforts are unsuccessful, and the mixed symptoms of the early undifferentiated disorder slide into a more chronic phase, typically developing both the more specific symptoms of other types and symptoms of increasing negativity.

**Catatonic Type** Though catatonic reactions may appear with dramatic suddenness, a patient usually has a background of eccentric behavior, often accompanied by some degree of withdrawal from reality. Though at one time common in Europe and North America, catatonic reactions have become less frequent in recent years.

The central feature of **schizophrenia, catatonic type,** is pronounced motor symptoms, either of an excited or a stuporous type, which sometimes make for difficulty in differentiating this condition from a psychotic mood disorder. The clinical picture is often an early manifestation of a disorder that will become chronic and intractable unless the underlying process is somehow arrested.



*This painting was made by a male patient diagnosed as suffering from undifferentiated schizophrenia. Over a period of about nine years, he did hundreds of paintings in which the tops of the heads of males were always missing, though the females were complete. Although the therapist tried several maneuvers to get him to paint a man's head, the patient never did.*

Some catatonic patients alternate between periods of extreme stupor and extreme excitement, sometimes quite violent, but in most cases one reaction or the other is predominant. In a study of 250 people diagnosed as suffering from catatonic schizophrenia, Morrison (1973) found that 110 were predominantly withdrawn, 67 were predominantly excited, and 73 were considered "mixed." No significant differences were found between these groups with regard to age, sex, or education.

During a catatonic stupor, a person loses all animation and tends to remain motionless in a rigid, unchanging position—mute and staring into space—sometimes maintaining the same position for hours or even days, until the hands and feet become blue and swollen because of immobility. One patient felt that he had to hold his hand out flat because the forces of "good" and "evil" were waging a "war of the worlds" on his hand, and if he moved it, he might tilt the precarious balance in favor of the evil forces. Surprisingly, despite their seeming withdrawal and apparent lack of attention to their surroundings, catatonic individuals may later give detailed accounts of events that were going on around them.

Some of these patients are highly suggestible and will automatically obey commands or imitate the actions of others (echopraxia) or mimic their phrases (echolalia). If a patient's arm is raised to an awkward and uncomfortable position, he or she may keep it there for minutes or even hours. Ordinarily, patients in a catatonic stupor stubbornly resist any effort to change their position and may become mute, resist all attempts at feeding, and refuse to comply with even the slightest request. They pay no attention to bowel or bladder control and may drool. Their facial expression is typically vacant, and their skin appears waxy. Threats and painful stimuli have no effect, and they may have to be dressed and washed by nursing personnel.

Catatonic patients may pass suddenly from states of extreme stupor to great excitement, during which they seem to be under great "pressure of activity" and may become violent, being in these respects indistinguishable from some bipolar manic patients. They may talk or shout excitedly and incoherently, pace rapidly back and forth, openly indulge in sexual activities, attempt self-mutilation or even suicide, or impulsively attack and try to kill others. The suddenness and extreme frenzy of these attacks make such patients dangerous to both themselves and others. These excited states may last a few hours, days, or even weeks, if sedating medication is not administered. The following case illustrates some of the symptoms typical of catatonic reactions:

Todd Phillips, a 16-year-old high school student, was referred to a psychiatric hospital by his family physician. His family had been very upset by his increasingly strange behavior over the preceding eight months. They had consulted their family physician, who treated him with small doses of antipsychotic medication, without any improvement.

Although Todd has had many problems since he was a small child, there was a distinct change about eight months ago. He began spending more and more time in his room and seemed uninterested in doing many of his usual activities. His grades dropped. He started stuttering. He used to weigh about 215 pounds, but began to eat less, and lost 35 pounds. For no reason, he started drinking large quantities of water.

More recently, there was a change for the worse. A few months ago he began taking Tai Chi lessons and often stood for long periods in karatelike positions, oblivious to what was going on around him. He stopped doing his homework. He took an inordinately long time to get dressed, eat his meals, or bathe. Before getting dressed in the morning he would go through an elaborate ritual of arranging his clothes on the bed before putting them on. When his parents asked him a question, he repeated the question over and over and did not seem to hear or understand what was said.

At school he received demerits for the first time for being late to class. His family began to lose patience with him when he eventually refused to go to school. When his father tried to get him out of bed in the morning, he lay motionless, sometimes having wet the bed during the night. It was at this point that his parents, in desperation, consulted their family physician.

When first seen in the hospital, Todd was a disheveled looking, somewhat obese adolescent, standing motionless in the center of the room with his head flexed forward and his hands at his sides. He appeared perplexed, but was correctly oriented to time and place. He was able to do simple calculations, and his recent and remote memory were intact. He answered questions slowly and in a peculiar manner. An example of his speech follows:

Q: Why did you come to the hospital?

A: Why did I come? Why did I come to the hospital? I came to the hospital because of crazy things with my hands. Sometimes my hands jump up like that . . . wait a minute . . . I guess it's happening. . . . Well, yes, see it's been happening (making robotlike gestures with his hands).

Q: What thoughts go through your head?

A: What thoughts go through my head? What thoughts go through my head? Well, I think about things . . . like . . . yes, well . . . I think thoughts . . . I have thoughts. I think thoughts.

Q: What thoughts?

A: What thoughts? What kinds of thoughts? I think thoughts.

Q: Do you hear voices?

A: Do I hear voices? I hear voices. People talk. Do I hear voices? No. . . . People talk. I hear voices. I hear voices when people talk.

Q: Are you sick?

A: Am I sick? No I'm not sick . . . these fidgeting habits, these fidgeting habits. I have habits. I have fidgeting habits.

Throughout the examination he made repetitive chewing and biting motions. Occasionally, when questioned, he would smile enigmatically. He seemed unresponsive to much of what was

*Peculiar posturing is a defining feature of the catatonic subtype of schizophrenia.*

going on around him. His infrequent movements were slow and jerky, and he often assumed the karatelike postures that his parents described, in which he would remain frozen. If the examiner placed the patient's hands in an awkward position the patient remained frozen in that position for several minutes. (Spitzer et al., 1983, pp. 139–40)

Although the matter is far from settled, some clinicians interpret a catatonic patient's immobility as a way of coping with his or her reduced filtering ability and increased vulnerability to stimulation: It seems to provide a feeling of some control over external sources of stimulation, though not necessarily over inner ones. Freeman (1960) has cited the explanation advanced by one patient: "I did not want to move, because if I did everything changed around me and upset me horribly so I remained still to hold onto a sense of permanence" (p. 932).

**Disorganized Type** Compared with the other subtypes of schizophrenia, **schizophrenia, disorganized type,** usually occurs at an earlier age and represents a more severe disintegration of the personality. Fortunately, it is considerably less common than the other forms. In pre-DSM-III classifications, this type was called *hebephrenic* schizophrenia.

Typically, an affected person has a history of oddness, overscrupulousness about trivial things, and preoccupation with obscure religious and philosophical issues. Frequently, he or she broods over the dire results of masturbation or minor infractions of social conventions. While schoolmates are enjoying normal play and social activities, this person gradually becomes more seclusive and more preoccupied with fantasies.

As the disorder progresses, the person becomes emotionally indifferent and infantile. A silly smile and inappropriate, shallow laughter after little or no provocation are common symptoms. If asked the reason for his or her laughter, the patient may state that he or she does not know or may volunteer some wholly irrelevant and unsatisfactory explanation. Speech becomes incoherent and may include considerable baby talk, childish giggling, a repetitious use of similar-sounding words, and a derailing of associated thoughts that may give a punlike quality to speech. In some instances, speech becomes completely incoherent, a "word salad."

Hallucinations, particularly auditory ones, are common. The voices heard by these patients may accuse them of immoral practices, "pour filth" into their minds, and call them vile names. Delusions are usually of a sexual, religious, hypochondriacal, or persecutory nature, and they are typically changeable, unsystematized, and fantastic. For example, one woman insisted not only that she was being followed by enemies but that she had already been killed a number of times. Another claimed that a long tube extended from the Kremlin directly to her uterus, through which she was being invaded by Russians.

In occasional cases, individuals become hostile and aggressive. They may exhibit peculiar mannerisms and other bizarre forms of behavior. These behaviors may take the form of word salad; facial grimaces; talking and gesturing to themselves; sudden, inexplicable laughter and weeping; and in some cases an abnormal interest in urine and feces, which they may smear on walls and even on themselves. Obscene behavior and the absence of any modesty or sense of shame are characteristic. Although they may exhibit outbursts of anger and temper tantrums in connection with fantasies, they are indifferent to real-life situations, no matter how horrifying or gruesome the latter may be. The clinical picture in disorganized schizophrenia is exemplified in the following interview:

> The patient was a divorcee, 32 years of age, who had come to the hospital with bizarre delusions, hallucinations, and severe personality disintegration. She had a record of alcoholism, promiscuity, and possible incestuous relations with a brother. The following conversation shows typical hebephrenic responses to questioning.
>
> Doctor: How do you feel today?
>
> Patient: Fine.
>
> Doctor: When did you come here?
>
> Patient: 1416, you remember, doctor (silly giggle).
>
> Doctor: Do you know why you are here?
>
> Patient: Well, in 1951 I changed into two men. President Truman was judge at my trial. I was convicted and hung (silly giggle). My brother and I were given back our normal bodies 5 years ago. I am a policewoman. I keep a dictaphone concealed on my person.
>
> Doctor: Can you tell me the name of this place?
>
> Patient: I have not been a drinker for 16 years. I am taking a mental rest after a "carter" assignment or "quill." You know, a "penwrap." I had contracts with Warner Brothers Studios and Eugene broke phonograph records but Mike protested. I have been with the police department for 35 years. I am made of flesh and blood—see doctor (pulling up her dress).
>
> Doctor: Are you married?
>
> Patient: No. I am not attracted to men (silly giggle). I have a companionship arrangement with my brother. I am a "looner". . . a bachelor.

The prognosis is generally poor if a person develops disorganized schizophrenia. To at least some extent, the disorganized variety of schizophrenia may be regarded as the "last stop" on a downward-coursing path of process schizophrenic psychosis. At this point, no form of treatment intervention yet discovered has a marked likelihood of effecting more than a modest recovery.

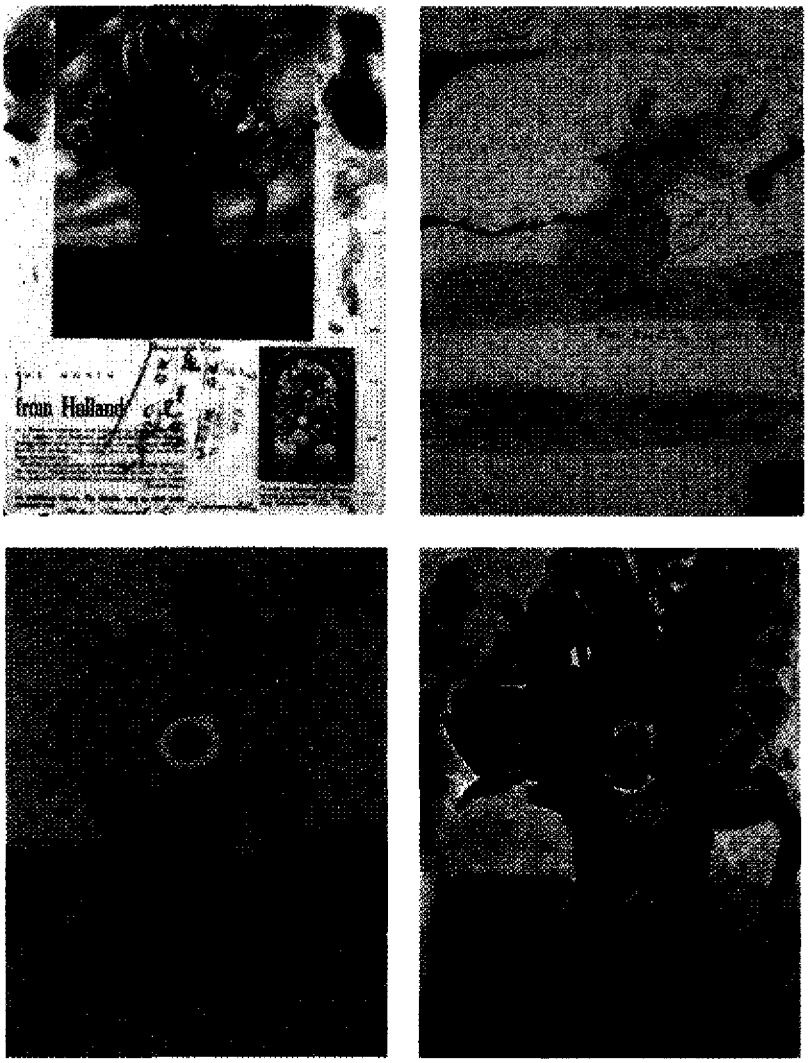
**Paranoid Type** Formerly about one-half of all schizophrenic first admissions to hospitals were diagnosed as **schizophrenia, paranoid type.** In recent years, however, the incidence of the paranoid type has shown a substantial decrease, while the undifferentiated type has shown a marked increase. The reasons for these changes are unknown.

Frequently, paranoid-type schizophrenic persons show histories of increasing suspiciousness and of severe difficulties in interpersonal relationships. The eventual symptom picture is dominated by absurd, illogical, and often changing delusions. Persecutory delusions are the most frequent and may involve a wide range of bizarre ideas and plots. An individual may become highly suspicious of relatives or associates and may complain of being watched, followed, poisoned, talked about, or influenced by various tormenting devices rigged up by "enemies."

In addition to persecutory themes, themes of grandeur are also common in paranoid-type delusions. Persons with such delusions may, for example, claim to be the world's greatest economist or philosopher, or some prominent person of the past, such as Napoleon, the Virgin Mary, or even Jesus Christ. These delusions are frequently accompanied by vivid auditory, visual, and other hallucinations. Patients may hear singing, or God speaking, or the voices of their enemies, or they may see angels or feel damaging rays piercing their bodies at various points.

An individual's thinking and behavior become centered on the themes of persecution, grandeur, or both in a pathological "paranoid construction" that—for all its distortion of reality—provides a sense of identity and importance perhaps not otherwise attainable for the person. There thus tends to be a higher level of adaptive coping and of cognitive integrative skills in a paranoid-type schizophrenic person than in other schizophrenic individuals. This relative preservation of intact cognitive functioning is undoubtedly one of the important bases for the paranoid-nonparanoid distinction noted earlier and regarded as important by many clinicians and researchers.

Despite this seeming relative "advantage" that paranoid-type schizophrenic individuals enjoy, such people are far from easy to deal with. The weaving of delusions and hallucinations into a paranoid construction results in a loss of critical judgment and in erratic, unpredictable behavior. In response to a command from a "voice," such a person may commit violent acts. Thus, paranoid schizophrenic patients can sometimes be dangerous, as when they attack people they are convinced have been persecuting them. Somewhat paradoxically, such problems are exacerbated by the fact that such people show less bizarre behavior and less extreme withdrawal from the out-



*A patient diagnosed as a paranoid schizophrenic was unable to respond at all when asked by a therapist to make an original drawing. Therefore, with the therapist's help, a picture (top left) was selected from a magazine for the patient to copy. One of his first attempts (top right) was a pencil drawing on manila paper showing great visual distortion, as well as an inability to use colors and difficulty in using letters of the alphabet. The evident visual distortion was a diagnostic aid for the therapist, who was able to learn from it that the patient, who was extremely fearful, saw things in this distorted way, aggravating his fear. In the picture at bottom left, the patient has shown obvious improvement, although it was not until a year after therapy began that he was able to execute a painting with the realism of the picture at bottom right.*

side world than individuals with other types of schizophrenia; as a consequence, they are less likely to be confined in protective environments.

The following conversation is between a clinician and a man diagnosed as a chronic paranoid schizophrenic. The case illustrates well the illogical, delusional symptom picture, together with continued attention to misinterpreted external data, that these individuals experience:

Doctor: What's your name?

Patient: Who are you?

Doctor: I'm a doctor. Who are you?

Patient: I can't tell you who I am.

Doctor: Why can't you tell me?

Patient: You wouldn't believe me.

Doctor: What are you doing here?

Patient: Well, I've been sent here to thwart the Russians. I'm the only one in the world who knows how to deal with them. They got their spies all around here though to get me, but I'm smarter than any of them.

Doctor: What are you going to do to thwart the Russians?

Patient: I'm organizing.

Doctor: Whom are you going to organize?

Patient: Everybody. I'm the only man in the world who can do that, but they're trying to get me. But I'm going to use my atomic bomb media to blow them up.

Doctor: You must be a terribly important person then.

> Patient: Well, of course.
>
> Doctor: What do you call yourself?
>
> Patient: You used to know me as Franklin D. Roosevelt.
>
> Doctor: Isn't he dead?
>
> Patient: Sure he's dead, but I'm alive.
>
> Doctor: But you're Franklin D. Roosevelt?
>
> Patient: His spirit. He, God, and I figured this out. And now I'm going to make a race of healthy people. My agents are lining them up. Say, who are you?
>
> Doctor: I'm a doctor here.
>
> Patient: You don't look like a doctor. You look like a Russian to me.
>
> Doctor: How can you tell a Russian from one of your agents?
>
> Patient: I read eyes. I get all my signs from eyes. I look into your eyes and get all my signs from them.
>
> Doctor: Do you sometimes hear voices telling you someone is a Russian?
>
> Patient: No, I just look into eyes. I got a mirror here to look into my own eyes. I know everything that's going on. I can tell by the color, by the way it's shaped.
>
> Doctor: Did you have any trouble with people before you came here?
>
> Patient: Well, only the Russians. They were trying to surround me in my neighborhood. One day they tried to drop a bomb on me from the fire escape.
>
> Doctor: How could you tell it was a bomb?
>
> Patient: I just knew.

Although it is true, as we have seen, that many paranoid schizophrenic individuals have histories of gradual onset and long-lasting difficulties in interpersonal relationships and productive functioning, it is also true that few of them show the true process pattern of schizophrenia (Ritzler, 1981). Sometimes, indeed, onset is quite rapid and occurs in individuals with entirely adequate pasts.

**Other Schizophrenic Patterns** The remaining subcategories of schizophrenia contained in DSM-IV deserve brief mention. **Schizophrenia, residual type,** which is the fifth officially recognized type of schizophrenia, is a category used for people who have experienced an episode of schizophrenia from which they have recovered sufficiently so as not to show prominent psychotic symptoms. They nevertheless still manifest some mild signs of their past disorder, such as odd beliefs, flat affect, or eccentric behavior.

As was noted in Chapter 6, the term **schizoaffective disorder** (bipolar or depressive subtype) is applied to individuals who show features of both schizophrenia and severe affective disorder. In the DSM-IV classification, this disorder is not listed as a formal subtype of schizophrenic disorder, although it is placed under that rubric.

**Schizophreniform disorder,** which shares an indistinct taxonomic status identical to that of schizoaffective, is a category reserved for schizophrenia-like psychoses of less than six months' duration. It may include any of the symptoms described in the preceding sections, but is probably most often seen in an undifferentiated form. Brief psychotic states of this sort may or may not be related to subsequent psychiatric disorder (Strakowski, 1994). At present, however, all recent-onset cases of true schizophrenia presumably must first receive a diagnosis of schizophreniform disorder. Because of the possibility of an early and lasting remission in a first episode of schizophrenic breakdown, prognosis for schizophreniform disorder (where it is a manifestation of recent-onset schizophrenic symptoms) is better than for established forms of schizophrenia, and it appears likely that by keeping it out of the formal category of schizophrenic disorder the potentially harmful effects of labeling may be reduced.

## Causal Factors in Schizophrenia

Despite an enormous research investment going back many years and continuing to the present day, the causal factors underlying the schizophrenias remain unclear, particularly in their details. Primary responsibility has been attributed variously to (a) biological factors; (b) psychosocial factors, including pathogenic interpersonal and family patterns, and decompensation under excessive stress; and (c) sociocultural factors, especially as influences on the types and incidence of schizophrenic disorders. These three sets of factors are not mutually exclusive, of course, and it seems likely that each is involved in at least some cases. We will discuss biological factors first and in relatively greater detail because of the prominence they have attained in contemporary thinking about schizophrenia, and also because of the related high activity and ferment currently occurring in this area of research.

**Biological Factors in Schizophrenia** Research relating to biological factors implicated in the causal pattern leading to schizophrenia has been concentrated on heredity and on various biochemical, neurophysiological, and neuroanatomical processes. Each of these reseach foci will be discussed in what follows.

*Heredity.* In view of the disproportionate incidence of schizophrenia in the family backgrounds of index schizophrenic patients (that is, the diagnosed group of people who provide the starting point for inquiry), genetic factors are believed to play an important causal role in many instances of the disorder. Though the evidence is persuasive, it remains circumstantial in that it is difficult to disentangle from possibly detrimental environmental factors, making for problems in precisely quantifying the genetic contribution in the causal pattern leading to the disorder. In addition, researchers have largely been frustrated in their attempts to identify the mechanisms involved in the genetic factor's influence in the production of schizophrenic behavior.

The questions raised here are serious ones, in part because we remain dependent on essentially pedigree strategies for demonstrating the genetic effect. No specific gene or chromosomal gene locus has as yet been identified as being reliably implicated in schizophrenia (Kendler & Diehl, 1993), and many investigators believe this ongoing search will continue to prove frustrating based on an increasing likelihood of ***polygenic*** involvement. That is, current thinking emphasizes the notion of a multiplicity of genes operating in concert to enhance the schizophrenia risk (Gottesman, 1991). Therefore, the knowledge we have been able to glean thus far is based entirely on findings of higher-than-expected rates of schizophrenia among biological relatives of schizophrenic persons, where these rates are regularly observed to increase with increases in the closeness of the blood relationship (i.e., in gene-sharing or consanguinity). We begin our review with studies conducted on twins.

*Twin Studies.* The general strategy of twin studies was discussed in Chapter 3 and more specifically in relation to anxiety and mood disorders in Chapters 5 and 6. As in the mood disorders, schizophrenia concordance rates for identical twins are routinely, and over very many studies, found to be significantly higher than those for fraternal twins or ordinary siblings.

Although the incidence of schizophrenia among twins is no greater than for the general population, study after study has shown a higher concordance for schizophrenia among identical (monozygotic—MZ) twins over people related in any other way, including fraternal (dizygotic—DZ) twinship. Depending on a variety of factors, the degree of this difference varies substantially from one study to another. One source of potential confusion in this area is the investigators' choice of emphasizing the "pairwise" versus the "probandwise" method of calculating concordance rates. By the former method, each concordant pair is counted only once; in the probandwise method a given concordant pair may be counted twice, provided the inclusion in the study of each twin of a pair was determined independently of the other. For technical (and readily defended) reasons, geneticists favor the probandwise method. Most abnormal psychology students, in our experience, grasp more easily pairwise concordance figures, and for this reason we report pairwise figures in what follows. It should be understood that these may somewhat underestimate the magnitude of genetic influence.

We are fortunate in having available a review of the premier worldwide literature on twin studies in schizophrenia, recently published by Torrey and colleagues (1994). Considering only the eight most adequately conducted of such studies, the overall pairwise concordance rate for schizophrenia in MZ twins is 28 percent; that is, the likelihood of finding schizophrenia in a monozygotic co-twin of a schizophrenic proband is approximately 28 in 100 worldwide. The corresponding figure for DZ twinships is 6 percent. By adopting even more stringent standards and including the data of only the three most rigorous studies thus far conducted, these concordance figures become 26 and 8 percent, respectively. Although these rates appear not exceptionally high in absolute terms, they nevertheless convey a powerful message. Given one co-twin who is schizophrenic, a reduction in shared genes from 100 percent to (approximately) 50 percent is associated with a three- to fivefold decrease in the schizophrenia risk. Also, 50 percent gene-sharing with a schizophrenic proband is associated with a risk level some six to eight times greater than that of the general population.

If schizophrenia were exclusively a genetic disorder, the concordance rate for identical twins would, of course, be 100 percent. In fact, however, there are more discordant than concordant pairs, notwithstanding the remarkable example of the Genain sisters. On the other hand, concordance of significant magnitude clearly exists, and twin studies show us that predisposition for the disorder is associated with genetic variables. Interpretation of this finding, however, is not completely straightforward, in part because common environmental factors might also be implicated in the occurrence of concordant outcomes. The environments, both prenatal and postnatal, of identical twins will be more similar *on average* than the environments of individuals sharing any other type of relationship. There is evidence, for example, that the occurrence of challenging life events is significantly correlated in twin pairs, and more so in MZs than DZs (Kendler et al., 1993b); that is, MZs are more like each other not only genetically, but also in the amount of stress they experience.

Other factors also complicate the picture. A good example of these interpretive hazards is provided in studies of identical twins who are discordant for the diagnosis of schizophrenia. These are sets of twins in which one member of the pair meets diagnostic criteria for schizophrenia but the other does not over some period of time during which he or she may be considered still at risk. By rendering the genetic variable constant, such a strategy has the potential of revealing possible nongenetic factors critical in the development of schizophrenia. Unfortunately, this ideal turns out to be difficult, perhaps impossible, to realize. As pointed out by Torrey and colleagues (1994), we can be certain that "identical" twins are identical only at the moment of the original splitting of the zygote. From that point on, recent studies show, a host of influences may intervene that could differentially affect the development of the two embryos. These include chromosomal changes and gene mutations, differences in circulation and oxygenation, differential response on exposure to infectious agents and to drugs and chemicals, and congenital brain anomalies.

To be sure, these potentially disruptive conditions, when they occur, are more likely to be shared by MZ than by DZ twins, but there are ample instances of unshared effects in MZ pairs (see Pollin & Stabenau, 1968; Suddath et al., 1990). If any such effects were to make an *independent* (i.e., nongenetic) contribution to enhanced risk for schizophrenia, as seems conceivable, it compromises the clarity with which we can draw genetic etiologic conclusions from the classical twin study method. That is, the higher concordance rate for schizophrenia in MZ than in DZ twins might be a consequence, at least in part, of a higher rate of shared pathogenic factors *other than* tainted genes. Another possibility is that shared genes produce an anomalous condition, which then may or may not adversely affect the twins' development to the same degree. In short, the classical twin method of investigation, in schizophrenia at least, poses significant problems as to the meaning of results obtained, especially in consideration of divergent outcomes with respect to MZ twins.

*These monozygotic (genetically identical) twin sisters are discordant for schizophrenia, which has affected only the twin on the right. Not uncommon, discordance affords an opportunity for certain types of research on the causes of schizophrenia.*

By far the most thorough and searching of available investigations of concordant and discordant psychopathological outcomes among MZ twins was the centerpiece of a recent report published by Torrey and colleagues (1994), to which reference has already been made. We can do no more here than selectively summarize the relevant major findings of this book-length work, concentrating our attention on 27 pairs of MZ twins who were discordant for schizophrenia. Below are listed the main statistically significant differences that differentiated the schizophrenic from the nonschizophrenic co-twins over the 27 pairs.

- Approximately 30 percent of the discordant affected twins were described as having been "different" during early childhood (e.g., shy and withdrawn, aggressive, or odd). Many of these differences were suggestive of early central nervous system dysfunction.

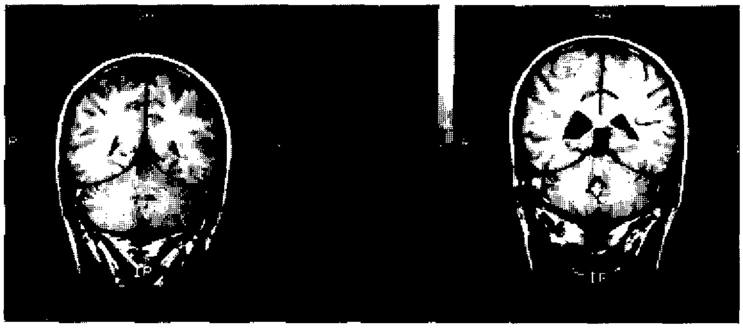
- Discordant affected twins showed widespread changes in brain structure, in particular bilateral decrements in size of the hippocampus-amygdala. However, changes in brain structure were uncorrelated with clinical aspects of the disorder.
- Discordant affected twins showed prominent alterations in brain function as assessed by cerebral blood flow, neuropsychological tests, neurological examination, and smooth pursuit eye movement (see p. 466). Reduced blood flow to the frontal lobes ("hypofrontality") was especially prominent and was associated with reduced size of the anterior hippocampus. Moderate or severe cognitive impairment in neuropsychological tests was observed in 14 of the 27 affected twins. The nonschizophrenic co-twins of discordant pairs, while less neurologically impaired than their disordered siblings, were more impaired than a set of normal control MZ twins.
- When schizophrenic persons from discordant and concordant pairs are compared, no significant differences in clinical or potential etiologic variables are found.

These results would seem to establish beyond reasonable doubt that genetically identical individuals can manifest widespread biological differences, particularly in neurological integrity, that are associated with relative risk for the development of schizophrenia. It should be noted, however, that none of the findings is of sufficient magnitude to predict outcomes for individual cases. Also, there were a few striking inconsistencies in the data, such that in these few cases the "well" twin appeared more biologically compromised than his or her schizophrenic co-twin. As the authors acknowledge, the results of this study, while intriguing, in themselves provide no clear resolution of basic questions concerning the ultimate source or sources of vulnerability to the development of schizophrenia. They do, of course, strongly implicate neurological anomalies as often playing a role in the causal pattern.

Returning to the specific issue of genetic influences, a seemingly "cleaner" investigative strategy employing discordant twins was pioneered by Fischer (1971, 1973). Reasoning that genetic influence, if present, would show up in the *offspring* of the *nonschizophrenic* twins of discordant pairs, she found exactly that outcome in a search of official records in Denmark. Gottesman and Bertelson (1989), in a follow-up of Fischer's subjects, have reported an age-corrected schizophrenia incidence rate (that is, a rate taking into account predicted breakdowns for subjects not yet beyond the age of risk) of 17.4 percent for the offspring of the nonschizophrenic monozygotic twins. This rate, which far exceeds normal expectancy, was not significantly different from that for offspring of the schizophrenic members of discordant pairs, or from that for offspring of schizophrenic dizygotic twins. Assuming that exposure to schizophrenic aunts and uncles would have, at most, limited etiologic significance, these results give impressive support to the genetic hypothesis. They also, as the authors note, indicate that the implicated predisposition may remain "unexpressed" (as in the nonschizophrenic twins of discordant pairs) unless "released" by unknown environmental factors.

*Adoption Studies.* Several studies have attempted to overcome the shortcomings of the twin method in achieving a true separation of hereditary from environmental influences by using what is called the adoption strategy. In one version of this strategy, concordance rates of schizophrenia are compared for the biological and the adoptive relatives of persons who have been adopted out of their biological families at an early age (preferably at birth) and have subsequently become schizophrenic. If rates of schizophrenia are greater among the patients' biological than adoptive relatives, a hereditary influence is strongly suggested; the reverse pattern would of course argue for environmental causation.

Heston (1966) was apparently the first to use one of several variants of this basic method. In a follow-up study of 47 people who had been born to schizophrenic mothers in a state mental hospital and placed with relatives or in foster homes shortly after birth, Heston found that 16.6 percent of these subjects were later diagnosed as schizophrenic. In contrast, none of the 50 control subjects selected from among residents of the same foster homes—whose biological mothers were not schizophrenic—later became schizophrenic. In addition to the greater probability of being diagnosed schizophrenic, Heston found that the offspring of schizophrenic mothers were more likely to be diagnosed as mentally retarded, neurotic, and psychopathic (that is, antisocial). They also had been involved more frequently in criminal activities and had spent more time in penal institutions. These findings suggest that the genetic liability is not specific to schizophrenia but also includes a liability for other forms of psychopathology.



*MRI scans of monozygotic twins. In the schizophrenic twin (right), the brain's ventricles are larger than in the normal twin's brain (left).*

Independent of Heston's work, a large-scale and multifaceted adoption study was undertaken in Denmark with American investigators working in collaboration with Danish professionals (Kety, 1987; Kety et al., 1968, 1978, 1994; Rosenthal et al., 1968; Wender et al., 1974). The well-publicized results of these studies, arguing the case for a genetic contribution to schizophrenia, have had an enormous impact on the field. We concentrate here on the most recent follow-up report (Kety et al., 1994), in which certain anomalies noted earlier in the data of the study (see Carson & Sanislow, 1993) appear to have been overcome. Using a national sample of schizophrenic adoptees and their biological and adoptive relatives (together with suitable control cases), the data show a preponderance of schizophrenia in the ***biological*** relatives of schizophrenic adoptees. Specifically, the diagnosis of "chronic schizophrenia" was ten times more frequent in these relatives than in the biological relatives of nonschizophrenic control adoptees. By contrast, adoptive relatives of schizophrenic adoptees had an unremarkable incidence rate for schizophrenia.

The problems associated with the original reports of this study, which included use of vague, pre-DSM-III diagnostic criteria, had actually been resolved to an extent prior to Kety and colleagues' (1994) most recent update. Procedurally, the improvement involved an independent reanalysis of the study's primary data. This reanalysis, conducted by Kendler and Gruenberg (1984), included the rediagnosis of all cases using DSM-III criteria and the use of other more advanced techniques to improve precision. Kendler and Gruenberg found convincing evidence of a modest genetic contribution to a certain class of disorders having schizophrenia-like features. They included, in addition to schizophrenia, schizotypal, and paranoid personality disorders; the three together were said to constitute a "schizophrenia spectrum," a group of disorders believed to share a common, genetically determined diathesis. Thus, as Heston's early work had suggested, the vulnerability conveyed by genetic influences appeared here not to be specific for schizophrenia per se but to involve a broader range of compromised functioning.

The Kendler and Gruenberg (1984) study has also recently been updated and expanded to the Danish population at large. In this later work (Kendler, Gruenberg, & Kinney, 1994a) the focus shifted to adoptees having DSM-III diagnoses of schizophrenia, schizotypal personality disorder, and schizoaffective (but mainly schizophrenic symptoms) disorder because these diagnoses were found to have maximum levels of (biological) family coherence. The notion of "schizophrenia spectrum" disorders was thus adjusted somewhat from the earlier study. The results again showed a concentration of spectrum diagnoses in the biological relatives of adoptees having these same diagnoses.

The Danish adoption studies did not include independent assessments of the child-rearing adequacy of the adoptive families into which index (those who became schizophrenic) and control (those who did not) youngsters had been placed. It remained for Tienari and colleagues (Tienari et al., 1985, 1987; Tienari, 1991) to add this feature to their research plan. This study, still in progress, involves a follow-up of the adopted-away children of all women in Finland hospitalized for schizophrenia, beginning in 1960. Of the 306 index (children whose mothers were schizophrenic) and control (comparable children whose mothers were normal) adoptees evaluated as of the latest (Tienari, 1991) available report, there were only five instances of psychosis or severe personality disorder (the report does not distinguish between these) among either index ($n = 55$) or control ($n = 68$) children who were raised in adoptive families independently rated to be psychologically "healthy." Two of these five cases were in fact controls, the offspring of normal mothers. Of the adoptees raised in families considered disturbed, 38 of 83 (46 percent) index children and 24 of 100 (24 percent) controls had become either psychotic or severely personality disordered.

Supporting earlier work, these results show a moderate genetic effect—the differential "healthy" and "severe disorder" rates of index versus control adoptees irrespective of family context. The magnitude of that effect, however, is actually exceeded by one associated with the variable of relative family disorganization. Tienari (1991) interprets these results as indicating an interaction between genetic vulnerability and an unfavorable family environment in the causal pathway leading to schizophrenia, an idea that seems plausible and not inconsistent with the genetic evidence already reported. Unfortunately, however, we cannot be certain that the emergence of odd or psychotic behavior in adoptees did not precede and cause, in whole or in part, the disorganization of their adoptive families. Analyses to examine this possibility are reported to be in progress.

*Studies of High-Risk Children.* The research strategy of long-term monitoring of children known to be at high risk for schizophrenia (by virtue of having been born to a schizophrenic parent) is basically intended to identify the environmental factors that cause breakdown (or resistance to it) in predisposed people. As we have seen in Chapter 1, this strategy, pioneered by Mednick and Schulsinger (1968) and followed up by numerous additional research projects (for reviews see Cornblatt et al., 1992; Erlenmeyer-Kimling & Cornblatt, 1992; Garmezy, 1978a, 1978b; Neale & Oltmanns, 1980; Rieder, 1979; Watt et al., 1984), has thus far not paid off very well in terms of isolating specific environmental factors. In saying this, however, we must acknowledge both the enormous difficulties that attend long-term and complicated projects of this sort and our own admiration for those who undertake them.

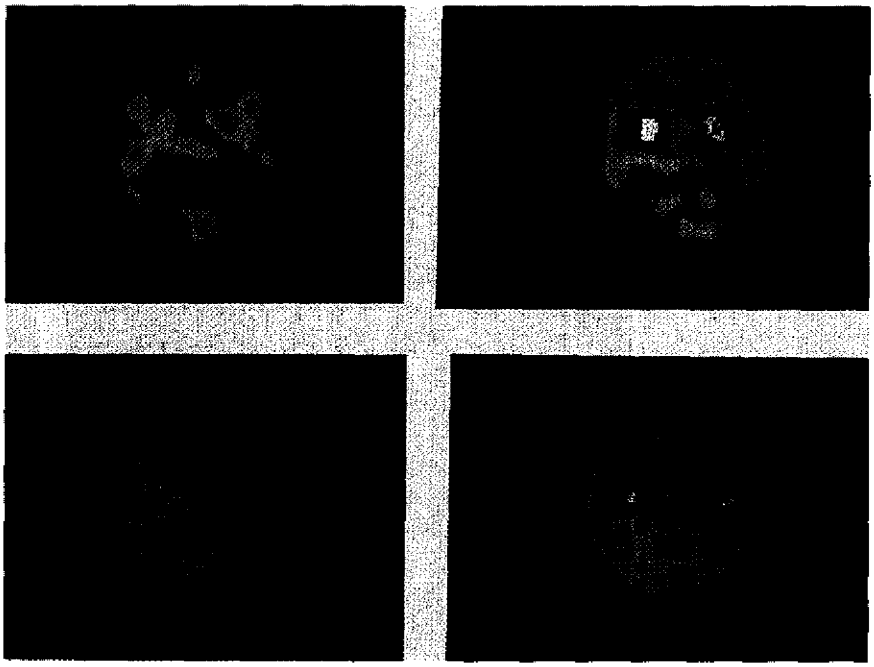
The difficulties are well illustrated in the first (and so far only) summary report of the Israeli-NIMH High-Risk Study (see Schizophrenia Bulletin, Vol. 11, No. 1, 1985). This project, begun in 1967, compared the outcomes of an index group of high-risk Israeli children who remained with their biological families to those brought up in the surrogate-parent settlement communities known as kibbutzim, relative to closely matched control groups of low-risk youngsters. "High risk" was defined as having a schizophrenic mother.

Many behavioral differences were found between index and control children, almost always favoring the controls; few were found for the variable of kibbutz versus normal rearing. Especially impressive was a high frequency of soft neurological signs (such as poor coordination) observed in index children in two separate examinations five years apart. On the critical measure of psychopathological outcome at 15 years following the beginning of the project (the average subject age was 25), rearing context proved apparently significant, although only in index cases and in an unexpected direction. Considering only schizophrenia and schizophrenia "spectrum" diagnoses, 9 of 46 index cases and 0 of 44 control cases had become disordered; 6 of the 9 casualties had been kibbutz-reared and hence to a considerable degree isolated from exposure to a psychotic parent. These trends are, if anything, strengthened when other diagnoses are included. Mirsky and colleagues (1985), who report these data, speculate that kibbutz living tends to evoke symptoms (although only in predisposed individuals) because it precludes privacy and "escape."

It may be noted in passing that, once again in this study, the children considered at risk on grounds that were at least implicitly genetic (their mothers being schizophrenic) were discovered as a group to be mildly neurologically compromised in childhood. In light of our earlier discussion and the related Torrey and colleagues (1994) findings on discordant identical twins, we can by no means be certain that such compromise, which might itself be a causal factor in schizophrenic outcomes, was mediated by the inheritance of deficient genes. As in the discordant twin study, the neurologic impairment may have been caused by factors other than faulty inheritance.

Although the available results of high-risk studies have generally proven difficult to interpret, they have supported the observation that having a schizophrenic parent is a good predictor of psychological disorder, including schizophrenia. It seems likely that some of this predictability comes about as a result of the genetic transmission of vulnerability to schizophrenia.

Summing up, the question of genetic transmissibility of a predisposition to schizophrenia is not as easily answered as it may appear to be when first posed. We are convinced that some genetic influence does make certain individuals abnormally vulnerable to schizophrenia. The data indicate that no such genetic contribution to etiology is sufficient in itself to produce schizophrenia, and they provide no basis for concluding that such a contribution is a necessary condition



*PET scans of the Genain quadruplets suggest a possible psychosocial impact resulting from the early matching of two pairs of co-twins. The scans indicate comparatively more severe brain impairment for Hester and Nora. The large areas of blue and yellow show that their brains consume lower levels of glucose, one indicator of lessened brain activity. The orange spots on the scan of Iris and Myra suggest more normal energy usage. Yet it is Iris, originally "matched" with Hester, who has had the poorer clinical outcome than either Nora or Myra.*

for a schizophrenic outcome. Indeed, most people who develop schizophrenia have no close relatives who are also known to have had the disorder—although, as we shall see, some of these normal relatives may share biological anomalies statistically associated with a schizophrenia diagnosis. Based on the best available studies, the aggregate average risk of schizophrenia for *first-degree* (sharing 50 percent genes) relatives of index cases is 4.8 percent, approximately nine times the rate for control cases (Kendler & Diehl, 1993).

*Biochemical Factors.* The idea that serious mental disorders are due to "chemical imbalances" in the brain is now common. To be useful to clinicians and researchers, however, such an idea must be reformulated into hypotheses that are as explicit and specific as possible. We cannot effectively address the general question of possible biochemically based contributions to the onset or maintenance of schizophrenic behaviors in the absence of clues that tell us where to look and what to look for. At present, as in the case of the severe mood disorders, the search is governed largely by attempts to discover the site and nature of central nervous system effects induced by drugs that diminish the behavioral expression of the disorder. In general, drugs that do so are ones found to alter (by up- or down-regulation) the likelihood that a nerve impulse arriving at a synapse will cross the synapse and "fire" the next neuron in the chain.

In schizophrenia research, the most attractive of these specific ideas has been the **dopamine hypothesis** (Sacher et al., 1978; Snyder, 1978), based on the observation that all of the early antischizophrenic drugs (called neuroleptics) had the common property of blocking dopamine-mediated neural transmission. Dopamine is a neurotransmitter like norepinephrine, of which it is a chemical precursor. It appears to be the main neurotransmitter for perhaps a half-dozen identified brain pathways. According to the dopamine hypothesis, then, schizophrenia is the product of an excess of dopamine activity at certain synaptic sites. Variants of this view include hypotheses that a schizophrenic person has too many postsynaptic dopamine receptors or that these receptors have for some reason become supersensitive. In recent years, however, the dopamine hypothesis has proved inadequate as a general formulation of etiology (Carlsson, 1988; Koreen et al., 1994; Lieberman & Koreen, 1993).

Dopamine-blocking drugs, for example, are therapeutically nonspecific for schizophrenia (that is, they are also used effectively to treat psychotic symptoms associated with various other disordered states, such as neuropsychological disorders, some manias, and even drug-induced "bad trips"). Additionally, the receptor-blocking effect is accomplished too quickly (within hours) to be consistent with the clinical picture of a gradual improvement (often over several weeks) following initiation of neuroleptic drug therapy in schizophrenia. In other words, if only excess dopamine activity were the cause of schizophrenia, these drugs should have ameliorative effects almost immediately; they do not. Moreover, their therapeutic activity depends not so much on curtailing excessive dopaminergic activity as on reducing it to *abnormally* low levels, which creates additional problems of an often serious nature (e.g., tardive dyskinesia; see Chapter 16, p. 610). In light of these and other observations, Davis (1978) has suggested that some other (unspecified) factor causes schizophrenia, the symptoms of which are then amplified by dopaminergic neural transmission.

More recent research has provided no serious challenge to this view, although it has shown the dopaminergic systems within the brain to be far more complicated than was originally thought. For example, we now know that more than one type of dopamine receptor site exists on the dendrites of postsynaptic neurons, and that these are involved in differing biochemical processes. The dopamine hypothesis has also been weakened by the emergence of the second-generation antipsychotic drug clozapine. The side effects of this drug have a profile that is very different from that of the dopamine blockers, suggesting that its antipsychotic mode of action significantly differs from that of the neuroleptics. Clozapine has a potent and early-appearing antipsychotic effect for approximately 30 percent of those schizophrenic patients showing little or no response to standard neuroleptic medication (Kane et al., 1988), and the proportion of patients responding positively continues to increase to a maximum of 50–75 percent for up to six months or more of continuing clozapine therapy (Lieberman et al., 1994; Meltzer, 1992).

Other biochemical theories of schizophrenia have been, and doubtless will continue to be, advanced, but to date no other such theory appears anywhere near as promising as had the dopamine theory through much of the past 25 years (Lieberman & Koreen, 1993). The fact is that the brain chemistry of schizophrenia remains very imperfectly understood. Ultimately, it seems likely that a complete understanding of the biochemistry of these disorders will have to include a sense of how other influences may interact with whatever biochemical abnormalities are discovered to accompany schizophrenic behavior.

*Neurophysiological Factors.* Much recent research has focused on the role of neurophysiological disturbances in schizophrenia, such as an imbalance in various neurophysiologic processes and inappropriate autonomic arousal. Such disordered physiology would disrupt normal attentional and information-processing capabilities, and there seems to be a growing consensus that disturbances of this type underlie the cognitive and perceptual distortions characteristic of schizophrenia.

A substantial proportion of schizophrenic persons are found to be deficient in their ability to track a moving target visually, a skill referred to as smooth pursuit eye movement, or SPEM (Levy et al., 1983, 1993; Lieberman et al., 1993a). The deficiency is sometimes attributed to a disorder of nonvoluntary attention. An impressive amount of evidence also indicates that many close relatives of schizophrenics share this SPEM deficit (e.g., Clementz et al., 1992; Iacono et al., 1992; Kuechenmeister et al., 1977; Levy et al., 1994)—far more in fact than share the diagnosis (Levy et al., 1993). This would suggest an inherited source for the difficulty while simultaneously ruling it out as a specific indicator for the disorder. Earlier research in this area has been well reviewed by Neale and Oltmanns (1980), and follow-up studies have continued to establish the reliability of the phenomenon (e.g., Holzman et al., 1988; Iacono et al., 1992). Many researchers (e.g., Braff, 1993; George & Neufeld, 1985; Neale & Oltmanns, 1980) believe that a deeper analysis of such deficits might enhance our understanding of hallucinations and other of the more dramatic phenomena of schizophrenia. Progress on this front, however, will require analysis of what is unique to schizophrenia in producing the SPEM deficit, since the gross deficit itself is also shared by psychotic mood-disordered subjects (Sweeney et al., 1994).

Some findings that may be related indicate that persons who are merely "at risk" for schizophrenia often experience difficulties in maintaining attention, in processing information, and in certain other indicators of cognitive functioning before a schizophrenic breakdown (Buchsbaum et al., 1978; Cornblatt & Keilp, 1994; Dworkin et al., 1993; Erlenmeyer-Kimling & Cornblatt, 1978; Fish et al., 1992; Marcus et al., 1985, 1993; Mednick, 1978; Silberman & Tassone, 1985; Spring & Zubin, 1978). Also possibly related are certain anomalies shown by many schizophrenic persons in electroencephalographic (brain wave) reactions to momentary sensory stimulation (Friedman & Squires-Wheeler, 1994; Pritchard, 1986), recently demonstrated in subjects merely at risk for the disorder by virtue of having somewhat peculiar thought processes (Stelmack, Houlihan, & McGarry-Roberts, 1993). Neurologic abnormalities, such as reflex hyperactivity and deficit performance in neuropsychological testing, have also been found in the close relatives of schizophrenic individuals (Kinney, Woods, & Yurgelun-Todd, 1986; Kremen et al., 1994).

Additional research literature, going back many decades, documents an enormous variety of other ways in which attentional and cognitive processes seemingly dependent on intact neurophysiologic functioning are disrupted among schizophrenic persons. As even our brief review shows, the disjointed array of findings reported remains baffling in the absence of a conceptual framework within which the "pieces" of the schizophrenia puzzle can be put together. Ideally, such an overarching conception would incorporate the correlative findings in close relatives and other nonschizophrenic "at risk" subjects. As yet, however, the role of these abnormalities in the development of schizophrenia remains unclear.

Abnormal neurophysiological processes in schizophrenia could be genetic in origin, but some at least could also be the product of biological deviations caused by other factors, as suggested in the discordant MZ twin data reviewed earlier. Problems of this sort could as likely arise from unknown intrauterine conditions or mechanical difficulties in the birth process as from faulty genes. Obstetrical complications in the histories of people who later become schizophrenic appear to be well above normative expectations (Cannon et al., 1993; Gureje, Bamidele, & Raji, 1994; Torrey et al., 1994), although it is possible that resultant early brain injury contributes to schizophrenic outcomes only among genetically predisposed persons (see Marcus et al., 1993). Such observations have led to a resurgence of interest in an old question—that of the anatomical intactness of the schizophrenic brain—to which we now turn.

*Neuroanatomical Factors.* Research on the structural properties of the brain in living subjects was difficult until the development of modern computer-dependent technologies, such as computerized axial tomography (CAT) and magnetic resonance imaging (MRI). The use of these techniques in the study of schizophrenic people's brains has developed at an accelerating pace in recent years, with interesting results.

Much evidence now indicates that in some cases of schizophrenia, particularly among those of chronic, negative-symptom course, there is an abnormal enlargement of the brain's ventricles—the hollow areas filled with cerebrospinal fluid lying deep within the core (Andreasen et al., 1982a, 1982b, 1986; Boronow et al., 1985; Carpenter et al., 1993; Goetz & Van Kammen, 1986; Gur & Pearlson, 1993; Gur et al., 1994; Pearlson et al., 1989; Raz, 1993). Several other associated anatomical anomalies, such as enlarged sulci (the fissures in the surface of the cerebral cortex), are often reported as well. In fact, the same anomalies are sometimes found in the "normal" family members of schizophrenic patients (Cannon & Marco, 1994; DeLisi et al., 1986b) and in the high-risk offspring of schizophrenic mothers (Cannon et al., 1993, 1994). In the latter instance, they appear to be associated with low birth weight and the possibility of fetal damage from some unknown agent, possibly infectious (Lyon et al., 1989; Silverton et al., 1985).

Because the brain normally occupies the rigid enclosure of the skull fully, enlarged ventricles imply a loss of brain tissue mass—possibly some type of atrophy or degeneration. Enlarged sulci have a similar significance. Some more direct evidence (e.g., Nestor et al., 1993) indicates deficient size of temporal lobe structures as well. Signs of what appears to be degeneration have been reported by Bernhardt, Meertz, and Schonfeldt-Bausch (1985) and Brown and colleagues (1986) in postmortem studies of the brains of individuals who had been schizophrenic. Bogerts (1993), however, in reviewing some 50 such studies going back many years, concludes that the findings are generally not consistent with the notion of progressive degeneration and favor the hypothesis of some type of anomaly in prenatal brain development.

The findings of an organic brain anomaly associated with some cases (overall about 50 percent exceeding the normal range, according to Cannon and Marco [1994]) is of enormous potential significance for at least the types of schizophrenia primarily implicated. Although it has been suggested that at least some of these brain abnormalities could be due to long-term use of antipsychotic medication (Breggin, 1990), examinations of the brains of schizophrenic people who have never taken therapeutic drugs show that this type of brain anomaly is not limited to patients having long histories of exposure to neuroleptic drugs (e.g., Lieberman et al., 1993b; Saykin et al., 1994; Weinberger et al., 1982). The observation of similar abnormalities among normal family members who have not taken drugs supports this finding.

The attention of brain researchers in schizophrenia has in recent years tended to focus on the frontal lobes, again with interesting results. These studies have mostly involved the positron emission tomography (PET) technique to measure metabolic activity at various sites in the brain while subjects are occupied with certain assigned tasks. Many recent studies have demonstrated abnormally low frontal lobe activation—called ***hypofrontality***—among schizophrenic persons when they engage in tasks supposedly requiring substantial frontal lobe involvement, such as the Wisconsin Card Sorting Test (WCST). Evidence of such hypofrontality has been reported for only the schizophrenic co-twins of discordant monozygotic twin pairs (Berman et al., 1992), for never-medicated patients (Buchsbaum et al., 1992), and especially for patients having high levels of negative versus positive symptoms (Andreasen et al., 1992; Wolkin et al., 1992). It should be cautioned, however, that the levels of "hypofrontality" observed among schizophrenic persons are often only marginally, albeit statistically significantly, different from levels observed in normal control subjects, with much overlap between the groups (e.g., Buchsbaum et al., 1992). Also, unlike persons with proven frontal-lobe damage, it appears that schizophrenic individuals who have difficulty with the WCST can be trained to perform normally on the instrument (Metz et al., 1994).

In an overall review of neuroimaging studies in schizophrenia, Gur and Pearlson (1993) conclude that the evidence implicates primarily three brain regions: the frontal, the temporolimbic (i.e., the temporal lobes and the adjacent, interior limbic system structures), and the basal ganglia (subcortical neural centers chiefly involved in integrative functions). These authors also note, however, that few of the findings are specific for schizophrenia, being also observed (usually in lesser degree) in other conditions such as the mood disorders. In any event, the conclusion of temporolimbic involvement is consistent with the types of deficit functioning observed in an extensive neuropsychological investigation of unmedicated, first-episode schizophrenic patients reported by Saykin and colleagues (1994).

While daunting problems of interpretation persist, these largely quite recent discoveries of brain anomalies in substantial numbers of schizophrenic patients are important not only in their own right but also because they invite integration with certain other exciting research initiatives of recent years. In particular, they relate to research on impaired neuropsychological test performances of schizophrenic people (Blanchard & Neale, 1994; Heaton et al., 1994; Levin & Yurgelun-Todd, 1989; Saykin et al., 1994) and to the already-noted neurologic impairments of some children who are at risk for schizophrenia (e.g., Dworkin et al., 1993; Fish et al, 1992; Marcus et al., 1993; Torrey et al., 1994). As suggested earlier, however, these brain abnormalities do not appear to be progressively developing ones (Bogerts, 1993; Heaton et al., 1994). Rather, it seems that these defects, often beginning before birth, enhance the risk for schizophrenia and are then detectable in substantial numbers of adult schizophrenic persons.

We should also note in this connection the evidence that many persons diagnosed as having a schizotypal personality pattern show behavioral deficits (such as poor perceptual-motor coordination or distinctive anomalies in reaction-time performance) suggestive of subtle neurological impairment (Lenzenweger, 1994; Lenzenweger & Korfine, 1994; Rosenbaum, Shore, & Chapin, 1988; Siever, 1985). This schizotypal pattern is conceived as one manifestation of a general schizophrenia "spectrum" of disorder and to render the person at risk for the full syndrome (Lenzenweger, 1994; Meehl, 1990).

For a number of years researchers have noted that people who become schizophrenic are more likely than people in general to have been born in the winter and early spring months—about an 8 percent deviation from norms (DeLisi, Crow, & Hirsch, 1986a). This peculiar observation, which itself is now beyond dispute, has given rise to a variety of hypotheses involving what has come to be called "the season of birth effect" in the development of schizophrenia. Some of these hypotheses directly relate to the question of compromised brain integrity in schizophrenia, as will be seen. In part because of that implication, the seasonal effect has been a source of sharp controversy. Lewis (1989a, 1989b, 1990; Lewis & Griffin, 1981), for example, has dismissed the original observation itself as a mere artifact of time spent at risk for persons affected. Lewis's analysis has been attacked (see issue #1 of the *Schizophrenia Bulletin* of 1990, Vol. 16), in our judgment none too effectively. Earlier on, however, Bradbury and Miller (1985), in a thorough review of the evidence then available, concluded that after correcting for the possible distortion, the evidence still pointed to some type of prenatal or early postnatal pathogenic influence associated with season, one that would bias development in favor of a schizophrenic outcome. Their best guess was some type of infectious process or obstetrical complications (or both).

Accumulating evidence suggests that Bradbury and Miller may have been on the right track. Several studies have suggested that, historically, influenza epidemics are associated at a higher-than-chance level with the gestation periods of persons who later became schizophrenic. The latest of these studies as of this writing, reported by Takei and colleagues (1994), identifies the supposedly critical peak infectious period as five months before birth, but includes the extremely curious finding that the association exists only for females, not males. Seemingly important and possibly related findings, recently reported by Torrey and colleagues (1993), establish a strong timewise correlation between the occurrence of stillbirths and the live births of persons who become schizophrenic, both being elevated in winter months. The investigators suggest that there appears to be a common factor for both stillbirths and schizophrenia risk, presumably some infectious agent; in the one case, according to this hypothesis, it leads to death of the fetus, while in the other to brain changes that enhance vulnerability to schizophrenia.

*Interpreting the Biological Evidence.* We trust the reader is by now convinced that the case for the role of biological factors in the etiology of schizophrenia has been established. The evidence for some sort of causal contribution from this broad source is, in a word, overwhelming. Impressive as it is, however, we remain in the dark about precisely how biological factors, operating either singly or in combination, are implicated in producing schizophrenic outcomes. Nor do we know which factors are most important—either in the aggregate or in individual cases.

In summary, then, biologically oriented research, particularly in recent years, has given us a wealth of new insights regarding the nature of schizophrenia and some of the sources of vulnerability to it. Our best bet at present is that it will prove not to provide a complete answer to the riddle of schizophrenia—that is, biological findings will have to be supplemented by pertinent psychosocial and sociocultural research in order to provide a comprehensive understanding, and eventually control, of the problem. This is hardly an extraordinary conclusion; the diathesis-stress model, which is often involved in characterizations of schizophrenia (Zubin & Spring, 1977), envisages exactly that sort of scenario. We turn now to an examination of the evidence relating to psychosocial influences in schizophrenia.

**Psychosocial Factors in Schizophrenia** Some behavioral scientists (e.g., Whitaker, 1992) dispute the idea that schizophrenia is caused primarily by biological factors. Noting that genetic and other biological factors are only part of the diathesis-stress combination, they emphasize the role of psychosocial factors in contributing to the disorder. Some researchers have argued that the proximate origins of the disorder are psychosocial; others have shown that psychosocial stress is related to the decompensation shown in schizophrenic episodes, whatever the role of biological factors in the underlying etiology of the disorder.

When we consider psychosocial influences, however, we are unlikely to see huge effects that dramatically alter the probability of someone becoming schizophrenic. In light of the frequency of abuse, trauma, and other less-than-ideal conditions of developmental experience, it is likely that truly potent and readily detected influences of this kind—if they existed—would already be well known. More realistically, we might hope to discover causal factors of small magnitude, ones that in combination with other pathogenic influences (including biological ones) might create added vulnerability to the point of exceeding some threshold beyond which any given person experiencing normal levels of stress may evidence psychosis.

It is, in our opinion, unfortunate and counterproductive that biological and psychosocial research are often conceived as mutually antagonistic, and that they rarely make contact with one another (Carson & Sanislow, 1993). One of us (Carson, 1991) has referred to this problem as one of widespread "tunnel vision" in the perspectives of scientists of both research camps. Although much lip service is paid to the evidence of interaction between biological and psychosocial variables in schizophrenia, studies that actually engage the interaction are rare.

One aspect of the imputed interaction is the often neglected fact that many of the biologically based deficits of the type reviewed in the preceding section would very likely influence the personality and social development of affected children in detrimental ways (see Zborowski & Garske, 1993). This idea has been a central element in the important contributions of psychologist Paul Meehl (1962, 1989, 1990a) in tracing the developmental course of schizophrenic outcomes. A recent ingenious series of studies reported by Walker and her colleagues (Grimes & Walker, 1994; Walker et al., 1993, 1994) illustrates how such interactions of the biological and the psychosocial might play themselves out.

These investigators gathered family home movies made during the childhoods of 32 persons who eventually succumbed to schizophrenia. Trained observers made "blind" (i.e., they were uninformed as to outcomes) ratings of certain dimensions of the emotional (Grimes & Walker, 1994) and facial expressions (Walker et al., 1993), motor skills, and neuromotor abnormalities (Walker et al., 1994) of these children and of their healthy-outcome siblings from the same movie clips. The facial and emotional expressions, and the motor competence, of the preschizophrenic and the healthy-outcome children were found by the raters to differ significantly and in ways apparently disadvantageous to the former group. The preschizophrenic children showed less—and less positive than negative—emotion, had poorer motor skills, and showed a higher rate of peculiar movements suggestive of neuromotor abnormalities. In other words, these children, in some instances before age two, were already showing behavioral abnormality not unlike that encountered in our earlier discussion of biological factors in schizophrenia. It is a reasonable hypothesis, therefore, that these preschizophrenic children as a group suffered from subtle neurological impairment of unknown origin.

Evidence already reviewed indicates that (a) these early-appearing subtle impairments are probably not progressive, and (b) they do not inevitably eventuate in a diagnosis of schizophrenia. It seems possible, however, that if persistent, they might affect transactions with the social environment in a disadvantageous manner and hence have negative effects on various aspects of personality development and functioning. The child who rarely manifests joy (even on celebratory family occasions such as birthdays), whose emotional expressiveness is prevailingly in the bland to negative range, who is motorically clumsy or awkward, and who may evidence peculiar involuntary movements, is likely to have a far less stress-free early life than the child endowed with the opposite characteristics. Minimally, such a scenario suggests that the occurrence of challenging life events ("stress") is not independent of a potentially pathogenic biological "diathesis."

Conceptual support for this admittedly speculative interpretation is provided in another recent study by Dworkin and colleagues (1993) involving interviews of normal children having a schizophrenic parent (and therefore being "at risk"). Compared with children of mood-disordered and normal parents, these youngsters were found to have more "affective deficits" and social incompetence, which were in turn associated, respectively, with observed neuromotor and attentional dysfunctions. Commenting on the increasing evidence of personality factors possibly mediating between biological liabilities and schizophrenic outcomes, Berenbaum and Fujita (1994) urge that researchers pay more attention to these likely psychosocially based contributions to the emergence of schizophrenic behavior, including findings of widespread personality deviations in relatives.

In making these comments, Berenbaum and Fujita (1994) address an issue that, in our judgment, is a serious one. We refer to the fact that research on psychosocial factors in the development of schizophrenia has been exceedingly sparse in recent years, especially compared with the research investment in biological correlates. As a result, much of the available psychosocially oriented research in schizophrenia is seriously dated. Much of it is also of poor quality, in part because it was planned and carried out in an era of less rigorous standards, and one in which less was in fact known about the proper design of research studies. It could also be argued that as a general rule research on psychosocial variables is inherently more complex and difficult than biologically oriented research. For these reasons, our discussion of psychosocial factors in schizophrenia will be relatively brief.

*Pathogenic Parent-Child and Family Interactions.* Studies of interactions in families having schizophrenic offspring have focused on such factors as (a) "schizophrenogenic" (schizophrenia-causing) parents; (b) destructive marital interactions; and (c) faulty communication. The focus of research has shifted in recent years from parent-child to total family interactions. Before we proceed, however, let us take a moment to gain some perspective on this sensitive topic.

In the early years of attention to family variables in schizophrenia, parents were routinely assumed to have caused their children's disorders through hostility, deliberate rejection, or gross parental ineptitude. Many professionals blamed parents, and their feedback to them was often angry and insensitive, if not brutal. We hope that nothing in the following discussion appears to condone such attitudes. Most of the parents we have known, whether or not they experienced the "bad luck" (Meehl, 1978, 1989) of schizophrenia in a child, have done the best that could reasonably be expected, within the limits of their own situations, to foster their children's happiness and success. Some parents are cruel and abusive, but there is no evidence that such a pattern is especially associated with schizophrenic outcomes. Apart from the fact that blaming parents does not help and may indeed worsen matters, blame could only be based on an oversimplified and erroneous notion of how people come to be schizophrenic.

*"Schizophrenogenic" Parenting.* Beginning in the 1940s, studies examined the parents of schizophrenic persons, particularly (and prejudicially) the mothers of male patients. Termed **schizophrenogenic,** these mothers were characterized on uncontrolled clinical observational grounds as rejecting, domineering, cold, overprotective, and impervious to the feelings and needs of others (e.g., Fromm-Reichmann, 1948). Such a mother was said to reject her child and at the same time to depend on the child for her emotional satisfaction. For this reason, it was suggested, she tended to dominate, possessively overprotect, and smother the child—encouraging dependence on her. The characteristics attributed to the "schizophrenogenic mother" have also been alleged on the same weak grounds to be causally involved in many other types of offspring outcome—such as anorexia in girls and male homosexuality—so much so that the concept of the "schizophrenogenic mother," never supported by robust research, was largely abandoned by the 1970s.

Studies have shown a high incidence of emotional disturbances on the part of both mothers and fathers of schizophrenic persons. Kaufman and colleagues (1960) reported that a large proportion of both the mothers and fathers of 80 schizophrenic children and adolescents studied were emotionally disturbed: The mothers almost uniformly used psychotic-like defense patterns, and the fathers likewise used seriously maladaptive coping patterns. Other studies concerned with the mental health of schizophrenics' parents, reviewed by Hirsch and Leff (1975), came to basically similar conclusions.

As was indicated in Chapter 3, however, we cannot reasonably assume that disturbance always passes from parent to offspring; it can work in the other direction as well. Whatever the original source of the difficulty, it appears that once it begins the members of a family may stimulate each other to increasingly pathological behavior. For example, studies by Mishler and Waxler (1968) and Liem (1974) both found that parents' attempts to deal with the disturbed behavior of schizophrenic sons and daughters had pathological effects on their own behavior and communication patterns. In fact, the bidirectionality of effects may be the single most robust finding we have gleaned from studying the families of schizophrenic people.

*Destructive Family Interactions.* Of particular interest here is the work of Theodore Lidz and his associates, which continued over some two decades. In an initial clinical study of 14 families with schizophrenic offspring, Lidz, Fleck, and Cornelison (1965) failed to find a single family that was reasonably well integrated. Eight of the 14 couples lived in a state of severe chronic discord in which continuation of the marriage was constantly threatened—a condition the investigators called **marital schism.** The other six couples in this study had achieved a state of equilibrium in which the relationship was maintained at the expense of a basic distortion in family relationships; in these cases, family members entered into a "collusion" in which the seriously disturbed behavior of one or the other parent was redefined as normal. This pattern was referred to as **marital skew.** Lidz (1978) proposed that a major effect of such severe family disturbance is the encouragement of "egocentric cognitive regression" in children subjected to it. We remind the reader again that family disturbance does not lead to schizophrenia for the large majority of persons experiencing it, and the investigations reported made no attempt to assess biologically based predispositions among the schizophrenia casualties.

As was by deliberate selection the case in the families studied by Lidz and colleagues, schizophrenic people often have psychologically healthy siblings who were raised with them in the same families. How have these siblings escaped the presumed pathology of the family context? A possible answer is that they were not biologically predisposed. But it is also probably true, as emphasized by the Lidz group, that the subculture of a family is not constant—that every child raised within a family experiences a family pattern in many ways unique to him or her. Stabenau and Pollin (1968; Stabenau et al., 1965), taking a direct approach to this issue, studied families in which nontwin siblings were discordant for schizophrenia and for juvenile delinquency. They found that 17 of their 19 "psychopathology siblings" (9 of 10 for schizophrenic siblings alone), compared with only 2 of 29 controls, had encountered periods of maximum family crisis during the presumably critical period of early childhood. These crises, which were identified by the families themselves, included financial disasters, major parental strife, and depressive episodes in one or another parent, among other things. We cannot, of course, be certain that these results are free of retrospective memory distortion.

*Faulty Communication.* Gregory Bateson (1959, 1960) was one of the first investigators to emphasize the conflicting and confusing nature of communications among members of schizophrenic families. He used the term **double-bind communication** to describe one such pattern. In this pattern the parent presents to the child ideas, feelings, and demands that are mutually incompatible. For example, a mother may be verbally loving and accepting but emotionally anxious and rejecting; or she may complain about her son's lack of affection but freeze up or punish him when he approaches her affectionately. The mother subtly but effectively prohibits comment on such paradoxes, and the father is too weak and ineffectual to intervene. In essence, according to Bateson's etiologic hypothesis, such a son is continually placed in situations where he cannot win, and he becomes increasingly anxious; presumably, such disorganized and contradictory communications in the family come to be reflected in his own thinking. Unfortunately, no solid confirmation of the pathogenicity of double-bind communications has ever been reported.

Singer and Wynne (1963, 1965a, 1965b) linked the thought disorders in schizophrenia to two styles of thinking and communication in the family—amorphous and fragmented. The amorphous pattern is characterized by a failure in differentiation; here, attention toward feelings, objects, or people is loosely organized, vague, and drifting. Fragmented thinking involves greater differentiation but lowered integration, with erratic and disruptive shifts in communication. In their later research, Singer and Wynne (Singer, Wynne, & Toohey, 1978; Wynne, Toohey, & Doane, 1979) referred generally to "communication deviance" (or "transactional style deviance") as being at the heart of the purported negative effects parents have on their preschizophrenic children.

Following up on this research, Goldstein and his colleagues (Doane et al., 1981; Goldstein, 1985; Goldstein et al., 1978; Lewis, Rodnick, & Goldstein, 1981), in a longitudinal study employing a variant of the "high-risk" strategy (that is, subjects who had been psychological clinic patients, but not schizophrenic, as adolescents were followed into adulthood), confirmed such an effect. Specifically, they found that high parental communication deviance, measured during their children's adolescence, did indeed predict the occurrence of adult schizophrenic spectrum disorders among these offspring. A family atmosphere of negative affect appears to increase the likelihood of such outcomes. These findings, reviewed by Goldstein and Strachan (1987), are intriguing in controlling for reverse (schizophrenic) child-to-parent influence in the creation of parental deviance. However, the study's design cannot rule out the possibility of a common genetic influence affecting both parents and offspring, one leading to odd communication in parents and (independently) to schizophrenia in offspring.

The point just made illustrates the unfortunate fact that the interpretation of findings relating to potential psychosocial influences in causing schizophrenia is at least as difficult and hazardous as we found characteristic of many findings in the biological domain. Perhaps, as was suggested earlier, clearer answers might be forthcoming if both groups joined forces.

*Excessive Life Stress and Decompensation.* Brown (1972) found a marked increase in the severity of life stress during the ten-week period prior to a person's schizophrenic breakdown. Problems typically centered on difficulties in intimate personal relationships. Similarly, Schwartz and Myers (1977) found interpersonal stressors to be significantly more common among schizophrenic people than among members of a matched control group. We remind the reader also that life stressors, like schizophrenia itself, have been shown to have a higher co-occurrence rate in monozygotic twins than in ordinary siblings (Kendler et al., 1993b), thus suggesting that some part of the elevated concordance for schizophrenia in MZ twins may be due as much to shared stress as shared genes.

While the primary etiology issue remains clouded, we do know that relapse into schizophrenia following remission is associated with a certain type of negative communication, called **expressed emotion (EE),** directed at the patient by family members (Hooley, 1985; Miklowitz, Goldstein, & Falloon, 1983; Vaughn & Leff, 1976, 1981). Originally observed in Great Britain, the effect has also been demonstrated in the United States (Hooley, 1985; Vaughn et al., 1984). Two components appear critical in the pathogenic effects of EE: emotional overinvolvement with the patient, and excessive criticalness. Expressed emotion may be especially intense where family members harbor the view that the disorder and its symptoms are under the voluntary control of the patient (Weisman et al., 1993).

Significantly, EE tends to be associated with familial communication deviance as previously described (Doane et al., 1985; Goldstein, 1985; Miklowitz et al., 1986). Parker, Johnston, and Hayward (1988) pointed out that EE is most likely to occur where a former patient is highly disturbed, a circumstance that might itself prompt rehospitalization. The force of this criticism is mitigated by findings that EE predicts schizophrenia before its initial onset (Goldstein, 1985). Finally, early results from intervention attempts to reduce EE and associated behaviors in family members have been very encouraging in terms of relapse prevention (Falloon et al., 1985; Hogarty et al., 1986).

As we noted, the course of decompensation (deterioration, disorganization of thought and personality) in reactive (primarily positive-symptom) schizophrenia tends to be sudden, while that in process (primarily negative-symptom) schizophrenia tends to be gradual. The actual degree of decompensation may vary markedly, depending on the severity of stress and the makeup of the individual. The course of recovery or recompensation may also be relatively rapid or slow. Similarly, the degree of recovery may be complete, even leading to a better-adjusted person than before; it may be partial but sufficient or insufficient for adequate adjustment; or it may be nonexistent, with the individual eventually developing an intractable, chronic, prevailingly negative-symptom schizophrenia (see Fenton & McGlashan, 1994).

**Sociocultural Factors in Schizophrenia** Despite occasional assertions that incidence/prevalence rates for schizophrenia are basically invariant throughout the world, there is in fact a 10- to 20-fold variation in occurrence of the disorder in the various social groupings and geographic regions for which such epidemiologic data are available (Stevens & Hallick, 1992). That is, large deviations away from the worldwide mean are observed to occur in both directions. No satisfactory biological explanation for this variation has as yet been identified (Kirch, 1993), and the possibility that the differences reflect intercultural social factors pertinent to the emergence of schizophrenic psychoses cannot at present be ruled out (Torrey, 1987). Alas, we also have no satisfactory explanation for why some cultural factors might enhance the risk for schizophrenia, while others would seem to diminish it. We appear to have here, then, another of those fascinating puzzles that are so common in the study of schizophrenia.

Systematic differences in the content and form of schizophrenia between cultures and even subcultures have been documented by various investigators over many years. Often, cases within a particular subculture tend to have a distinctive form. Among the aborigines of West Malaysia, Kinzie and Bolton (1973) found the acute type to be by far the most common manifestation; they also noted that symptom content often "had an obvious cultural overlay, for example, seeing a 'river ghost' or 'men-like spirits' or talking to one's 'soul'" (p. 773). However, the clinical picture seems to be changing as rural Africans and other people from developing nations are increasingly exposed to modern technology and social change (Copeland, 1968; Kinzie & Bolton, 1973; Torrey, 1973, 1979).

An important consideration in cross-cultural studies is that opinions concerning what is normal or abnormal by professionals from another culture may not always correspond with the opinions held by members of the community in question (Butcher, Narikiyo, & Vitousek, 1993). For example, in describing the schizophrenic disorders of members of Hawaiians of Japanese descent professional observers emphasized seclusiveness and shallow, blunted emotionality. Other members of their own group, on the other hand, were impressed by evidence of uncontrolled emotionality and distrust, behaviors that are strongly counter to the community's values (Katz et al., 1978).

Focusing on sociocultural factors within our own society, Murphy (1968) early on summarized the abundant evidence that the prevalence of schizophrenia in the United States is inversely related to socioeconomic status: The lower the status, the higher the prevalence of schizophrenia. Although the data on this point are perhaps not as clear as Murphy and others have indicated (Sanua, 1969), his conclusion would be accepted as basically accurate by most contemporary investigators. Interestingly, a reverse effect seems to exist in India; there, the upper classes (castes) experience higher rates of schizophrenia than the lower classes (Torrey, 1979).

Although it has been suggested (Kohn, 1973) that the conditions of lower-class existence are themselves stressful and in addition impair an individual's ability to deal resourcefully with stresss, there is also compelling evidence that lower-class membership can be a result of schizophrenia. Affected individuals often drift downward on the socioeconomic ladder because the disorder impedes effective coping with ordinary life demands; many such cases may be found among the homeless mentally disordered. We should also emphasize that alleged ethnic differences in the prevalence and clinical pictures of schizophrenia—for example, between African Americans and Caucasians—disappear when social class, education, and related socioeconomic conditions are equated (Lindsey & Paul, 1989; Snowden & Cheung, 1990).

In concluding our review of the causal factors in schizophrenia, it may be pointed out that research on the causation of human behavior is, as the late David Shakow (1969) expressed it, "fiendishly complex," even with normal subjects:

> Research with disturbed human beings is even more so, particularly with those with whom it is difficult to communicate, among them schizophrenics. The marked range of schizophrenia, the marked variance within the range and within the individual, the variety of shapes that the psychosis takes, and both the excessive and compensatory behaviors that characterize it, all reflect this special complexity. Recent years have seen the complication further enhanced by the use of a great variety of therapeutic devices, such as drugs, that alter both the physiological and psychological nature of the organism. Research with schizophrenics, therefore, calls for awareness not only of the factors creating variance in normal human beings, but also of the many additional sources of variance this form of psychosis introduces. (Shakow, 1969, p. 618)

In general, and as Shakow implies, there appears to be no one clinical entity or causal sequence in schizophrenia. Rather we seem to be dealing with several types of psychologically maladaptive processes resulting from an interaction of biological, psychosocial, and sociocultural factors; the role of these factors undoubtedly varies according to the given case and clinical picture. Often the interaction appears to involve a vicious spiral that, once initiated, propels the person into a process of decreasing availability of coping resources in the face of increasing demands for performance adequacy. Some people panic and undergo a sort of psychobiological collapse; others appear to become gradually apathetic and demoralized, retreating from the unmanageable and perhaps (to them) unintelligible real world both physically and psychologically. Whatever the initial picture, outcomes are not at first notably predictable (Strakowski, 1994; Vaillant, 1978) and typically become more so only after weeks, months, or, in some cases of rapidly altering clinical pictures, even years.

## Treatments and Outcomes

For roughly a century before the 1950s the prognosis for schizophrenia was generally considered extremely unfavorable, even hopeless. Patients receiving the diagnosis, unless their families were wealthy and could afford the expense of private psychiatric hospitalization, were routinely shuttled to remote, forbidding, overcrowded, and environmentally bleak public hospitals. Once "safely" incarcerated they were treated—if at all—by poorly trained, overworked staff with ineffective techniques that were often, in addition, objectively cruel (e.g., straitjackets) or predictably terrifying (e.g., electroconvulsive "shock" therapy, as it was originally called). As often as not, perhaps after a brief trial at one of the pointless "therapies" offered, the patient was simply left to fashion a tolerable adjustment to an institution he or she was never expected to leave. Such an adjustment, long continued, would in most instances ensure the erosion of capacities and skills essential to self-maintenance outside of the institution. Thus, complying with the self-fulfilling prophecies of their dismal prognoses, most admitted patients, in fact, did not ever leave.

For most schizophrenic persons, the outlook today is not nearly so bleak. Improvement came with dramatic suddenness when the phenothiazine class of drugs—then referred to as "major tranquilizers"—were introduced in the mid-1950s. Pharmacotherapy (treatment by drugs), especially when combined with other modern treatment methods, permits most patients to be treated in outpatient clinics; a schizophrenic person who enters a mental hospital or other facility as an inpatient for the first time has an 80–90 percent chance of being discharged within a matter of weeks or, at most, months. The rate of readmission, however, is still extremely high, and many patients experience repeated discharges and readmissions in what is commonly referred to as the "revolving door" pattern. Exact figures on readmissions are difficult to calculate, however; the "careers" of individual patients are not readily tracked owing to general instability (Weinstein, 1983).

Overall, about 25 percent of schizophrenic patients in time recover permanently and without debilitating residual problems; only some 10 percent now show the classical pattern of inexorable deterioration and intractable, profound disability (M. Bleuler, 1978). The latter outcome, the most tragic and feared course a schizophrenic process may take, has thus not been completely eradicated with alterations in hospital practice and the availability of new treatment approaches. Here the downward spiral of increasing deficit, disorganization, preponderance of negative symptoms, and ultimately retreat from the human community still cannot be interrupted by any means known. In some instances the progression occurs remarkably rapidly, reaching a stable state of profound dilapidation in a year or less. More typically, the deteriorating course lasts for several years, normally stabilizing at a low functioning level within five years (M. Bleuler, 1978; Fenton & McGlashan, 1994; McGlashan & Fenton, 1993). Even in severe cases of maximally poor prognosis, however, the outlook may not be completely hopeless. Although the "course" may be as long as 40 years or more, recoveries may still occur, albeit rarely (M. Bleuler, 1978).

The rest of the people who experience a first schizophrenic episode—some 65 percent of the total—show varying degrees of personality impoverishment, oddities of thought and behavior, and episodic psychotic behavior. Obviously, this is the group most likely to show the "revolving door" pattern, with brief periods of hospitalization interspersed among more lengthy periods of sustainable but marginal living on the outside. Many of these persons become "street people," and some of them are too dysfunctional to take advantage of government social programs that may provide, for example, shelter, food, and minimal financial support. Abuse of "recreational" drugs may be a serious problem for this intermediate-outcome group, and such abuse is associated with increased likelihood of psychotic relapses (Linszen, Dingemans, & Lenior, 1994).

As we have done with respect to other disorders, we will postpone until later chapters a detailed discussion of the various kinds of treatment employed for schizophrenia. Here we note merely that, contrary to widespread belief, such treatment is—or should be—by no means limited to drugs. While antipsychotic medication has unquestionably been a boon in ameliorating some of the more disturbing symptoms of schizophrenia, the residual problems left unaffected can remain a very serious obstacle to full participation in society. Consider in this regard the remarks of the distinguished Harvard social psychologist Roger Brown, who attended a meeting of Schizophrenics Anonymous in order to familiarize himself with the problems of these people:

> [The group leader] began with an optimistic testimony about how things were going with him, designed in part to buck up the others. Some of them also spoke hopefully; others were silent and stared at the floor throughout. I gradually felt hope draining out of the group as they began to talk of their inability to hold jobs, of living on welfare, of finding themselves overwhelmed by simple demands. Nothing bizarre was said or done; there was rather a pervasive sense of inadequacy, of lives in which each day was a dreadful trial. Doughnuts and coffee were served, and then each one, still alone, trailed off into the Cambridge night.
>
> What I saw a little of at that meeting of Schizophrenics Anonymous is simply that there is something about schizophrenia that the antipsychotic drugs do not cure or even always remit on a long-term basis (Brown & Herrnstein, 1975, p. 641).

Unfortunately, Brown's assessment of the antipsychotic drugs is in our experience painfully accurate. The marked social deficits Brown so well describes are extremely common accompaniments of schizophrenic disorders and may indeed be more disabling in their continuously disruptive effects than an occasional eruption of psychotic symptoms. There is little evidence that long-term rates of *social* recovery from schizophrenia have been notably affected by the availability of these drugs (see Harding et al., 1987a, 1987b). HIGHLIGHT 12.3 summarizes a recent confirmatory review of overall treatment outcomes in schizophrenia during the past 100 years.

In light of available evidence of considerable psychosocial contribution to the etiology of schizophrenia, much of it reviewed in this chapter, we think it short-sighted to approach the treatment of this type of disorder from an exclusively biological perspective. In fact, a recent review of studies combining biological and psychological treatments for schizophrenia suggests that the combination of drugs plus psychosocial treatment measures is often superior to drugs alone (Klerman et al., 1994).

Several forms of psychosocial intervention in schizophrenia can claim at least modest empirical validation (Emmelkamp, 1994). These include a therapeutic community-based program having minimal professional oversight (Fairweather et al., 1969; Fairweather, 1980), a rigorous token economy program for chronic state hospital patients (Paul & Lentz, 1977), specialized individual psychotherapy provided by therapists highly experienced with this group (Karon & Vandenbos, 1981), social-skills training (Halford & Haynes, 1991), and family interventions designed to reduce high levels of expressed emotion (Tarrier & Barrowclough, 1990). Perhaps it is time to take another look at what carefully designed and evaluated psychosocial interventions have to offer in coping with this most baffling of psychopathological conditions.

## DELUSIONAL (PARANOID) DISORDER

The term **paranoia** has been in use a long time. The ancient Greeks and Romans used it to refer more or less indiscriminately to any mental disorder. Our present, more limited use of the term stems from the work of Kraepelin, who reserved it for cases showing delusions and impaired contact with reality but without the bizarreness, fragmentation, and severe personality disorganization characteristic of schizophrenia.

Currently two main types of psychoses are included under the DSM-IV headings relating to (nonschizophrenic) paranoid disorders: **delusional disorder,** formerly called paranoia or paranoid disorder, and **shared psychotic disorder,** in which two or more people develop persistent, interlocking delusional ideas. The latter condition, historically known as *folie à deux,* is described briefly in HIGHLIGHT 12.4. Brief episodes (i.e., lasting one month or less) of otherwise uncomplicated delusional thinking are included in the category "Brief Psychotic Disorder." Our focus in this section will be on delusional disorder. As there is little recent literature on this disorder, we will be forced to focus on a number of early studies. Because these studies used the traditional terminology *paranoia* and *paranoid disorder,* we will use those terms and the newer delusional disorder classification interchangeably.

DSM-IV requires that diagnoses of delusional disorder be specified by type, based on the predominant theme of the delusions present. These types are as follows:

> *Persecutory type.* The predominant delusional theme is that one (or someone to whom one is closely related) is being subjected to some kind of malevolent treatment, such as spying, stalking, or the spreading of false rumors of illegal or immoral behavior. Legal actions of one sort or another are often instituted to redress the alleged injustice, and in extreme cases more direct and dangerous modes of counteraction are employed,

12.3

## A Century of Treatments and Outcomes in Schizophrenia

Hegarty and colleagues (1994) have recently published an extraordinary study of worldwide clinical outcomes in treated schizophrenia on a decade-by-decade basis from 1895 through 1991. Using the technique of quantitative review on 320 studies (of a total of 821) meeting relatively stringent criteria of data quality, the clinical outcomes of 51,800 schizophrenic patients followed up for at least one year (311,400 person-years of follow-up in all) were assessed and reduced to common metric formats yielding overall "improved" versus "not improved" outcome status decisions. Placement in the "improved" category required the patient to have been described as "recovered, in remission, well without residual symptoms, minimally or mildly symptomatic, improved without significant deficit, socially recovered, or working or living independently" (p. 1410). For the most part, results are reported as weighted (for number) average percentages of patients declared "improved" for the various comparisons of interest.

The main results may be summarized as follows:

1. The overall proportion of patients considered improved over the entire century, independent of length of follow-up, was 40.2 percent.

2. There was a statistically significant variation in improvement rates over the decades examined (before 1916, 1916–25, 1926–35, 1936–45, 1946–55, 1956–65, 1966–75, 1976–85, and 1986–91).

3. The overall improvement rate in the period 1895–1915 was approximately 30 percent, falling to approximately 25 percent in the 1916–25 decade. Thereafter there was an increase to slightly under 40 percent, which was maintained over the three decades from 1926 to 1955. In the two decades comprising 1956–75 improvement rates increased again, remaining constant at about 50 percent. Improvement rates declined again in the 1976–85 decade, to approximately 46 percent. In the most recent and briefer period assessed, 1986–91 (six years), improvement rates declined again to about the level of the long 1926 to 1955 plateau—that is, about 38 percent.

4. These substantial variations in schizophrenia outcomes over the past century are not random. Strong inference indicates that they are determined by identifiable alterations over time in psychiatric practice. The abrupt and substantial two-decade elevation in improvement rates beginning in 1956 exactly coincides with the introduction and rapid adoption of the then-new antipsychotic drugs, such as chlorpromazine (Thorazine). The recent and continuing decline in improvement rates beginning with the 1976–85 decade may initially seem alarming, but it too has a straightforward explanation. Building through the 1970s, and culminating with the introduction of DSM-III in 1980, there was a pronounced trend toward the adoption of stricter criteria for the diagnosis of schizophrenia, such as requiring that the patient have exhibited psychotic symptoms over some minimal period prior to applying the diagnosis. These stricter criteria, sometimes called neo-Kraepelinian (as opposed to Bleulerian) and made progressively more stringent in DSM-III-R and DSM-IV, have the effect of limiting the diagnosis to more severely disturbed patients—such as those with increased levels of negative symptoms. Sicker patients are harder to treat effectively, and hence less likely to be improved on follow-up. In short, we have not lost therapeutic ground since 1976—only changed the rules of engagement, or more specifically the average severity of psychopathology in the patient group addressed.

such as attempted (and sometimes completed) murder.

*Jealous type.* The predominant theme is that one's sexual partner is being unfaithful.

*Erotomanic type.* The predominant theme is that some other person of higher status, frequently someone of considerable prominence, is in love with one and wants to start a sexual liaison.

*Somatic type.* The predominant theme is an unshakable belief in having some physical illness or disorder, often esoteric or exotic in nature.

*Grandiose type.* The predominant theme is that one is a person of extraordinary status, power, ability, talent, beauty, etc., or that one has a special relationship with someone having such attributes, usually someone of celebrity status.

*Mixed.* This diagnosis is used where there are combinations of the above but when no single theme predominates.

Of these types, the persecutory is by far the most common, and our discussion will focus on this form of the disorder.

12.4

## Folie à Deux: Shared Psychotic Disorder

A relatively neglected phenomenon in the psychoses is that of *folie à deux*—a form of psychological "contagion" in which one person copies and incorporates into his or her own personality functioning the delusions and other psychotic patterns of another person. (*Folie à deux,* the traditional term, has been relabeled "Shared Psychotic Disorder" in DSM-IV.) Familial relationships between individuals in 103 cases studied by Gralnick (1942) fell within one of the following four categories:

| | | | |
|---|---|---|---|
| sister | ⇄ | sister | 40 cases |
| husband | ⇄ | wife | 28 cases |
| mother | ⇄ | child | 24 cases |
| brother | ⇄ | brother | 11 cases |

Among the explanatory factors, all environmental, emphasized by Gralnick were (a) length of association, (b) dominance-submission, (c) type of familial relationship, and (d) prepsychotic personality. The high incidence in the husband-wife category is particularly striking because common heredity plays no part as an etiological factor in these cases.

In another study, Soni and Rockley (1974) reported on eight cases of *folie à deux* seen at a European hospital. Their findings supported those of Gralnick and emphasized the role of pathological prepsychotic characteristics, such as increased suggestability and submissive roles, as well as the type of relationship in explaining why these patients acquired their partner's delusions.

Although the formal diagnosis of delusional disorder is rare in clinic and mental hospital populations, this observation provides a somewhat misleading picture of its actual occurrence. Many exploited inventors, fanatical reformers, self-styled prophets, morbidly jealous spouses, persecuted teachers, business executives, or other professionals fall into this category. Unless they become a serious nuisance, these people are usually able to maintain themselves in the community and do not recognize their paranoid condition nor seek help to alleviate it. In some instances, however, they are potentially dangerous, and in virtually all instances they are inveterate "injustice-detectors," inclined to undertake retributive actions of one sort or another against their supposed tormenters.

## The Clinical Picture in Delusional Disorder

A paranoid, or delusional, individual feels singled out and taken advantage of, mistreated, plotted against, stolen from, spied on, ignored, or otherwise mistreated by "enemies." The delusional system usually centers on one major theme, such as financial matters, a job, an invention, an unfaithful spouse, or another life affair. For example, a woman who is failing on the job may insist that her fellow workers and superiors have it in for her because they are jealous of her great ability and efficiency. As a result, she may quit her job and go to work elsewhere, only to find friction developing again and her new job in jeopardy. Now she may become convinced that the first company has written to her present employer and has turned everyone against her so that she has not been given a fair chance. With time, more and more of the environment is integrated into her delusional system as each additional experience is misconstrued and interpreted in the light of her delusional ideas. See HIGHLIGHT 12.5 for a list of characteristics typical of paranoid thinking.

Although the evidence that paranoid people advance to justify their claims may be tenuous and inconclusive, they are unwilling to accept any other possible explanation and are impervious to reason. A husband may be convinced of his spouse's unfaithfulness because on two separate occasions when he answered the phone the party at the other end hung up. Argument and logic are futile. In fact, any questioning of his delusions only convinces him that his interrogator has sold out to his enemies. The following case illustrates the sometimes tragic results of paranoid delusions:

> Milner cited the case of a paranoid man, aged 33, who murdered his wife by battering her head with a hammer. Prior to the murder, he had become convinced that his wife was suffering from some strange disease and that she had purposely infected him because she wished him to die. He believed that this disease was due to a "cancer-consumption" germ. He attributed his conclusion in part to his wife's alleged sexual

## Sequence of Events in a Paranoid Mode of Thinking

A number of investigators have concluded that the most useful perspective from which to view paranoia is in terms of a ***mode of thinking***. The sequence of events that appears to characterize this mode of thinking may be summarized as follows:

1. *Suspiciousness*—the individual mistrusts the motives of others, fears he or she will be taken advantage of, and is constantly on the alert.
2. *Protective thinking*—the individual selectively perceives the actions of others to confirm suspicions and blames others for his or her failures.
3. *Hostility*—the individual responds to alleged injustices and mistreatment with anger and hostility and becomes increasingly suspicious.
4. *Paranoid illumination*—the moment when everything "falls into place"; the individual finally understands the strange feelings and events being experienced.
5. *Delusions*—the individual has delusions of influence and persecution that may be based on "some grain of truth," presented in a logical and convincing way; often, the later development of delusions of grandeur.

Over time, a paranoid individual may incorporate additional life areas, people, and events into the delusional system, creating a "pseudo-community" whose purpose is to carry out some action against him or her. Paranoid individuals who respond in this manner may come to feel that all the attention they are receiving from others is indicative of their unique abilities and importance, thus paving the way for delusions of grandeur.

Based in part on Meissner (1978) and Swanson, Bohnert, and Smith (1970).

> perversion and also gave the following reasons for his belief:
>
> 1. His wife had insured him for a small sum immediately after marriage.
> 2. A young man who had been friendly with his wife before their marriage died suddenly.
> 3. A child who had lived in the same house as his wife's parents suffered from fits. (He also believed that his wife's parents were suffering from the same disease.)
> 4. For several months before the crime his food had had a queer taste, and for a few weeks before the crime he had suffered from a pain in the chest and an unpleasant taste in the mouth. (1949, p. 130)

Although ideas of persecution predominate, many paranoid individuals develop delusions of grandeur in which they endow themselves with superior or unique abilities. Such "exalted" ideas usually center on messianic missions, political or social reforms, or remarkable inventions. Paranoid people who are religious may consider themselves appointed by God to save the world and may spend most of their time "preaching" and "crusading." Threats of fire and brimstone, burning in hell, and similar persuasive devices are liberally employed. Many paranoid people become attached to extremist political movements and are tireless and fanatical crusaders, although they often do their cause more harm than good by their self-righteousness and their highly strained condemnations of others.

Some paranoid individuals develop remarkable inventions that they have endless trouble in patenting or selling. Gradually they become convinced that a plot is afoot to steal their invention, or that enemies of the United States are working against them to prevent the country from receiving the benefits of their remarkable talents. Hoffman cited the case of a man who went to Washington to get presidential assistance in obtaining a patent for a flame thrower that, he claimed, could destroy all the enemies of the United States. He would patiently explain who he was: "There's God who is Number 1, and Jesus Christ who is Number 2, and me, I am Number 3" (1943, p. 574).

Aside from the delusional system, such an individual may appear perfectly normal in conversation, emotionality, and conduct. Hallucinations and the other obvious signs of psychopathology are rarely found. This normal appearance, together with the logical and coherent way in which the delusional ideas are presented, may make the individual most convincing, perhaps especially to persons awash in their own uncertainties. The following case is typical:

> An engineer developed detailed plans for eliminating the fog in San Francisco and other large cities by means of a system of reflectors that would heat the air by solar radiation and cause the fog to lift. The company for which he worked examined the plans and found them unsound. This rejection upset him greatly and he resigned his position, stating that the other engineers in the company were not qualified to pass judgment on any complex and advanced engineering projects like his. Instead of attempting to obtain other employment, he then devoted full time trying to find some other engineering firm that would have the vision and technical proficiency to see the great potential of his idea. He would present his plans convincingly but become highly suspicious and hostile when questions concerning their feasibility were raised. Eventually, he became convinced that there was a conspiracy among a large number of engineering firms to steal his plans and use them for their own profit. He reported his suspicions to the police, threatening to do something about the situation himself unless they took action. As a consequence, he was hospitalized for observation and diagnosed as suffering from paranoia.

The diagnosis of delusional disorder may be rendered difficult at times because of the unclarity of the term ***delusion***. It is not always possible to determine the truth or falsity of an idea, and some ideas that are patently false are held with sincerity and conviction by very many people. For this reason, formal definitions of "delusion" (as in DSM-IV) usually specify that an idea must be held as preposterous by the majority of a person's own community. As the example of Columbus's much ridiculed fifteenth-century belief that the earth was round shows, however, this qualification does not always solve the problem. These and other difficulties surrounding the notion of delusional thinking have received a thorough and much needed airing in a book edited by Oltmanns and Maher (1988). They suggest, incidentally, that delusional thinking is not so different from normal thinking as we would perhaps like to think. The problem also remains, of course, of differentiating delusional disorder from paranoid personality disorder (Chapter 9), which also involves a judgment call as to whether or not clearly eccentric and convoluted thinking merits the designation "delusional," that is, "psychotic." A clinician is well-advised in equivocal cases to be diligent in devising probes to test for magical elements in the "evidence" underlying the patient's paranoid constructions.

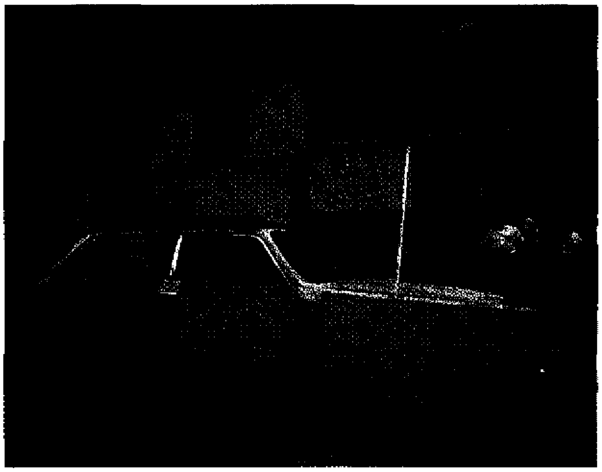
A patient's delusional system is apt to be particularly convincing if one accepts the basic premise or premises on which it is based. For example, where the delusional system develops around some actual injustice, it may be difficult to distinguish between fact and fancy. As a result, the individual's family and friends, as well as well-meaning public officials, may be convinced of the truth of the claims. However, the individual's inability to see the facts in any other light, typical lack of solid evidence for far-reaching conclusions, and hostile, suspicious, and uncommunicative attitude when the delusional ideas are questioned usually provide clues that something is wrong.

Paranoid individuals are not always as dangerous as popular fiction and drama suggest, but the chance always exists that they will decide to take matters into their own hands and deal with their enemies in the only way that seems effective. In one instance, a paranoid school principal became convinced that the school board was discriminating against him and shot and killed most of the board members. In another case, a paranoid man shot and killed a group of seven people he thought had been following him.

The number of husbands and wives who have been killed or seriously injured by suspicious, paranoid mates is extremely large worldwide (DeKay & Buss, 1992). As Swanson, Bohnert, and Smith (1970) have pointed out, such murderous violence is commonly associated with jealousy and the loss of self-esteem; the spouse feels that he or she has been deceived, taken advantage of, and humiliated, often on observational grounds that could more readily be interpreted as benign. Interestingly, the types of situations likely to evoke these murderous spousal attacks may be different for husbands and wives, according to a review and analysis by DeKay and Buss (1992); husbands are more sensitive to issues involving sexual infidelity, whereas wives react more to suspicion that the mate may have an alternate emotional attachment. Paranoid people may also, of course, get involved in violent and subversive activities, terrorism, and political assassinations. In many such instances we believe the concept of group paranoia to have considerable explanatory merit.

## Causal Factors in Delusional Disorder

Most of us on various occasions may wonder if we are not jinxed, when it seems as if everything we do goes wrong and the cards seem to be stacked against us. Many people go through life feeling underrated



*The insistent way the owner of this car has chosen to broadcast his or her ideas and the ideas themselves, which are hostile, suspicious, and a distortion of factual evidence, indicate delusional thinking.*

and frustrated, brooding over fancied and real injustices. Meissner (1978) regards such attitudes as a normal and essential phase of personality development, a necessary component in the achievement of personal identity and autonomy. Most people, according to this view, are able to grow beyond this phase, where a central feature is the need for an enemy. Some few are not, however, in which case they chronically entertain paranoid explanations of whatever problems they may have.

We have already noted that individuals with paranoid schizophrenia tend not to show the extensive cognitive disorganization seen in other forms of schizophrenia. Also, while the maintenance of a severely paranoid "fix" on the world does indeed require drastic contortions of a person's basic cognitive resources, it also requires that the person be relatively deft in dealing with the information the environment provides. If an individual were so impaired cognitively as to be unable to function on a day-by-day basis, the alertness and selectively efficient information processing essential to the effective maintenance of an organized delusional system would, of course, be unavailable. Implied in these observations is the idea that severe disruption of cognitive processes per se may not be implicated in the causal pattern leading to delusional, or paranoid, forms of psychosis, and might indeed be a factor that, if present, would discourage their development.

Most delusionally disordered persons seem as children to have been aloof, suspicious, seclusive, secretive, stubborn, and resentful of punishment. When crossed, they became sullen and morose. Rarely do these pre-paranoid individuals show a history of normal play with other children or good socialization in terms of warm, affectionate relationships (Sarvis, 1962; Schwartz, 1963; Swanson et al., 1970). The seeds may thus be sown quite early for a stand-offish and relatively unfriendly interpersonal style. Such a child may understandably be unpopular with peers—in effect, an aversive stimulus. Thus, as Lemert (1962) has noted, an unduly suspicious or coldly rejecting person frequently becomes a target of actual discrimination and mistreatment. Ever alert to injustices, both imagined and real, such an individual finds abundant "proof" of persecution.

In this context, Grunebaum and Perlman (1973) have pointed to the naivete of a pre-paranoid person in assessing the interpersonal world—in terms of who can be trusted and who cannot—as a fertile source of hurtful interactions. As they express it, "The ability to trust others realistically requires that the individual be able to tolerate minor and major violations of trust that are part of normal human relationships" (p. 32). The pre-paranoid individual is unprepared for the "facts of life," however, tending to both trust and mistrust inappropriately and to overreact when others are perceived, accurately or not, as betraying the trust.

Where delusional disorder develops, it usually does so gradually, as mounting failures and seeming betrayals force these individuals to an elaboration of their defensive structures. To avoid self-devaluation, they search for "logical" reasons for their lack of success. Why were they denied a much-deserved recognition or promotion? Why was it given to someone obviously far less qualified? They become more vigilant, begin to scrutinize the environment, search for hidden meanings, and ask leading questions. They ponder like a detective over the "clues" they pick up, trying to fit them into some sort of meaningful picture.

Gradually the picture begins to crystallize—a process commonly referred to as "paranoid illumination." It becomes apparent that they are being singled out for some obscure reason, that other people are working against them, that they are being interfered with. In essence, they protect themselves against the intolerable assumption, "There is something wrong with me," with the defensive transformation, "They are doing something to me." They have failed not because of any inferiority or lack on their part, but because others are working against them. They are on the side of good and the progress of humankind, while their enemies are allied with the forces of evil. With this as their fundamental defensive premise, they proceed to distort and falsify the facts to fit it and gradually develop a logical, fixed, delusional system. Cameron (1959) has referred to this process as the building up of a paranoid "pseudo-community" in which an individual organizes surrounding people (both real and sometimes imaginary) into a structured group whose purpose is to carry out some despicable or violent action against him or her.

The role of highly selective information processing in the development of these delusional systems should be emphasized. Once these individuals begin to suspect that others are working against them, they start carefully noting the slightest signs pointing in the direction of their suspicions and ignore all evidence to the contrary (Swanson et al., 1970).

With this frame of reference, it is quite easy, in our highly competitive and sometimes ruthless world, for paranoid persons to find ample evidence that others are working against them. This attitude itself leads to a vicious circle, for their suspiciousness, distrust, and criticism of others drive their friends and well-wishers away and keep them in continual friction with other people, generating new incidents for them to magnify. Often others do in fact find that they must conspire behind their backs in order to keep peace and cope with their eccentricities, thus adding additional evidence of foul play and victimization. When this feedback process spins out of control, as it too often does, tragic consequences may ensue.

## Treatments and Outcomes

We do not have established, empirically validated approaches for the treatment of delusional disorders. It is generally conceded that, once a delusional system is well established, it is extremely difficult to dismantle it by any of the treatment methods commonly employed by mental health professionals. It is usually impossible to communicate with such individuals in a rational way concerning their problems. In addition, they are not prone to seek treatment, which many would interpret as an admission of weakness, but are more likely to seek justice for all the wrong done to them.

An offer of medication—even if any genuinely promising ones were available—is very likely to be refused, and may indeed be woven into a delusional system involving conspiracy and intended harm. Nor is hospitalization likely to help, for delusionally disordered persons are likely to see it as a form of unjust incarceration and persecution. If forcibly hospitalized, they are apt to regard themselves as superior to hospital staff as well as other patients and will usually complain that their families and the staff have conspired to have them "put away" illegally and for no valid reason. Not uncommonly, they seek legal redress, and sometimes they are successful in gaining a court-ordered release, particularly if they have not as yet been charged with any crime. Seeing nothing wrong with themselves, they refuse to cooperate or participate in anything resembling "treatment."

Eventually, however, many hospitalized delusional persons realize that their failure to curb their actions or expression of their delusional ideas will result in prolonged hospitalization. As a result, they may make a pretext of renouncing their delusions, admitting that they did hold such ideas but claiming that they now realize the ideas are absurd and are giving them up. After their release, they are often more reserved in expressing their ideas and in annoying other people, but they are usually far from recovered. Thus the prognosis for complete recovery from paranoia has traditionally been unfavorable.

## UNRESOLVED ISSUES

### on Schizophrenia

The unresolved issues concerning schizophrenia are so manifold that a truly adequate accounting of them would require the better part of an additional chapter. We will point out, therefore, only a few of the many problems we encounter in this realm of psychopathology. Issues of treatment, in particular, will be postponed to Chapters 16 and 17.

A major hurdle confronts us at the outset in trying to come to grips with the nature of this disorder where the conceptual boundaries are both murky and shifting. While we have had, since the advent of DSM-III in 1980, a set of explicit defining criteria that when properly applied will permit us to say who is and who is not schizophrenic with a high degree of reliability, these criteria have continued to change in successive revisions of the manual.

We do not intend to suggest in taking this critical stance that we have a better set of criteria to offer. Rather, we suspect that tinkering with the definitional criteria for "schizophrenia" without having solid research data to support the effort will never produce a satisfactory solution, and it is unclear that such data can be produced in the absence of fundamental redirections of approach. What is needed is some sort of reconceptualization that enables us to view the pertinent phenomena in a new and more productive light. We feel reasonably certain that any such major conceptual advance will entail not one but many "schizophrenias." That is, it is likely that the class of people who merit this diagnosis is heterogeneous not merely in terms of manifest behavior (which is obviously the case), but also in terms of the nature and development of the sources of their aberrant behavior. An important implication is that there probably exists no single "core" condition. Another implication is that efforts at identification and differentiation of basic subgroups should have a high research priority. Beyond that, the crystal ball is notably hazy—in large part because of the sheer magnitude and diversity of the seemingly reliable observations researchers continue to place before us.

In the aggregate, those findings point to the likely operation of a host of moderating variables, at varying levels of observation from the biomolecular to the sociocultural, that influence outcomes with respect to every risk factor for schizophrenia so far discovered. That being the case, it would seem that the organization of our scientific efforts at unraveling the mysteries leaves much to be desired, because it consists in the main of separate camps of relatively narrow scientific disciplines, ones moreover with a history of rarely looking at what might be happening in other camps. Since the evidence suggests that the schizophrenias result from interactions among variables that cross traditional disciplinary boundaries, interdisciplinary isolation would seem a dysfunctional state of affairs. To put it another way, few if any individual investigators are prepared to deal with more than limited portions of this complicated matrix. For the future, the situation would seem to call for widespread, intensive collaboration among many different kinds of scientists in seeking solutions to what Gottesman and Shields (1982) have aptly termed the "epigenetic puzzle" of the schizophrenias.

Schizophrenia confronts society with massive problems of how to take care of people who seem unable, or unmotivated, to take care of themselves (neither institutionalization nor deinstitutionalization has worked, granting that neither has been competently managed), but most of its manifestations do not involve violence or danger to others. The delusional (paranoid) disorders, on the other hand, are associated often enough with acts of violence that they confront us once again with difficult questions relating to jurisprudence, civil rights, and appropriate measures, if any, of containment and intervention. As in the case of suicide, discussed in the Chapter 6, the professional mental health community needs direction from the larger society on what level of homicidal (or other violent) risk is tolerable in light of the uncertainty in predicting individual patients' behavior. Elimination or significant reduction of such uncertainty is not likely in the foreseeable future.

## SUMMARY

The schizophrenic disorders, involving largely psychotic phenomena, include some of the most extreme deviations to be found in the domain of psychopathology. Markedly heterogeneous in their organization, they manifest a profile of disordered functioning in the areas of language and communication, content of thought, perception, emotional expression, identity confusion, disrupted volition, autistic retreat, and pecularities of motor behavior.

One extraordinary case—that of the Genain quadruplets—sheds light on the sources and the complexity of schizophrenic disorders. All four of the Genain sisters became schizophrenic prior to the age of 25. After carefully tracking the progress of the Genains through the years, researchers have concluded that both biological and psychosocial factors contributed to their vulnerability to schizophrenia.

Classical subtypes of schizophrenia include undifferentiated (mixed symptoms not fitting into other categories or moving rapidly among them), catatonic (involving chiefly motor symptoms), disorganized (incoherent, silly, or inappropriate affect and behavior), and paranoid (persistent ideas or hallucinations regarding persecution or grandiosity, or other themes). Modern research has tended to focus on positive-symptom (hallucinations and delusions) versus negative-symptom (emotional blunting) schizophrenia. Given these variations as well as other anomalies, some have questioned whether such a "thing" as schizophrenia exists. The credence of such questions is enhanced by the uncertain validity of the diagnostic criteria for schizophrenia.

Hardly anybody questions the existence of a cluster of behaviors, called schizophrenic, that are unintelligible to the average person. Such behaviors have been correlated with biological, psychosocial, and sociocultural variables. As yet, however, none of these broad sources of behavioral variation has been definitely established as encompassing *the* sole etiologic factor in schizophrenia. In fact, no such single factor is likely to be responsible. The evidence at all levels of observation suggests that complex interactions involving numerous influences, probably different in different patients, are involved.

The delusional (paranoid) disorders, in which schizophrenic disorganization seems not to be a significant factor, form a subgroup of psychoses that are even less well understood than the others. A paranoid individual harbors ideas of persecution, grandiosity, both, or more rarely of other patently false content. The person, however, is entirely functional—including, often, highly organized cognitive functioning—in areas that do not impinge on the delusional thought structure (the paranoid construction) in which the person is centrally involved. These people can often function at a marginal level in society. Some of them, however, become dangerous, exposing problems at the interface between mental health professionals and society at large that continue unresolved. Treatment of chronically paranoid persons is currently difficult, at best.

# BRAIN DISORDERS AND OTHER COGNITIVE IMPAIRMENTS

*Freddie Brice,* Hole in the Head. *Brice (b. 1920), was born in Charleston, South Carolina. He was raised primarily by his mother, who worked in a cotton mill. After moving to New York to find work, primarily as a ship painter at the Brooklyn Navy Yard, Brice spent time in reform school, jail, and psychiatric hospitals. It was in a psychiatric day program that he learned to paint. He often sings and laughs while he works; "painting gives me joy," he says.*

SUMMARY
KEY TERMS

In contrast to most kinds of abnormal behavior, some problems arise partly as a consequence of structural defects in the brain tissue—many of them due to damage of one sort or another. Such damage typically involves loss of nerve cells (neurons) and can impair the brain's normal physiological functioning. As the brain is the organ of behavior, damage to it may disrupt effective thought, feeling, and action. The relationship of deficits associated with organic brain defects to abnormal behavior is complicated and often unclear. Accordingly, it seems wise at this point to digress slightly from the main task of clinical description to get a better understanding of brain damage and brain dysfunction.

When structural defects in the brain are present before birth or occur at an early age, mental retardation may result, its severity depending to a large extent on the magnitude of the defect. In mental retardation, a child fails to develop sufficient skills to cope adequately and independently with environmental demands. As we shall see, most mentally retarded people do not suffer from gross brain damage, but virtually all those who can be described as severely retarded have some form of demonstrable organic pathology. Other people who sustain prenatal or perinatal (that is, during birth) brain damage may experience normal mental development in most aspects of behavior, but suffer from specific cognitive or motor deficits, such as learning disorders or spasticity (excessive muscle contraction that impairs motor performance).

Sometimes the intact brain sustains damage after it has completed normal biological development. A wide variety of injuries, diseases, and toxic substances may cause the functional impairment or death of neurons or their connections, which may lead to obvious deficits in psychological functioning. In some cases such damage is associated with behavior that is not only impaired but also highly maladaptive—even psychotic. People who sustain serious brain damage after they have mastered the basic tasks of life are in a very different situation from those who start life with a deficit of this kind. When brain injury occurs in an older child or adult, there is a loss in established functioning. This loss—this deprivation of already acquired and customary skills—can be painfully obvious to the victim, adding an often pronounced psychological burden to the organic one.

In other cases the impairment may extend to the capacity for realistic self-appraisal, leaving these patients relatively unaware of their losses and thus poorly motivated for rehabilitation. Many victims may also have to cope with the idea of little improvement or, worse, with a prognosis involving inevitable progressive decline. The psychological impact in such cases can be devastating.

In this chapter we will first discuss those disorders that occur when the normal adolescent or adult brain has suffered significant organic impairment or damage, following which we will move to a consideration of compromised brain functioning that is either congenital or arises in the earliest phases of psychological development.

## BRAIN IMPAIRMENT AND ADULT DISORDER

Prior to the DSM-IV of 1994, most of the disorders to be considered in this section were called **organic mental disorders,** an outmoded term that failed to distinguish between the direct *neurological* consequences of brain injury, including various cognitive deficits, and the *psychopathological* problems sometimes accompanying such injury, such as depression or paranoid delusions. Since the latter types of abnormal "mental" phenomena are common in people with no demonstrable brain anomalies, the implication that they were in some other cases caused by brain damage was at best unproven and at worst possibly seriously misleading.

The destruction of brain tissue may involve only limited behavioral deficits or a wide range of psychological impairments, depending on (a) the nature, location, and extent of neural damage; (b) the premorbid (predisorder) personality of the individual; (c) the individual's total life situation; and (d) the amount of time since the first appearance of the condition. Although the degree of mental impairment is usually directly related to the extent of damage, in some cases involving relatively severe brain damage, mental change is astonishingly slight; in other cases of apparently mild and limited damage there may be profoundly altered functioning.

### Adult Brain Damage and Disordered Mental Functioning

The fundamental disorders we shall be dealing with in this section are always in the strictest sense *neuropsychological* ones, although psychopathological problems may be associated with them. Some "mental" symptoms in organic mental disorders are therefore the more or less direct product of the physical interruption of established neural pathways in the brain. The bases of these symptoms are relatively well understood, and the symptoms themselves have relatively constant features in people with comparable types of brain injury in terms of location and extent. For example, with mild to moderate *diffuse* (widespread) damage, such as might occur with moderate oxygen deprivation or the ingestion of toxic substances, attentional and self-monitoring impairments are quite common. Such a person, for example, may complain of memory problems due to an inability to sustain focused retrieval efforts, while showing an intact ability to store new information. Severe diffuse damage results in dementia, described later.

*Some brain diseases, Alzheimer's among them, can be diagnosed with certainty only at autopsy. Clinicians must be conscientious in their diagnostic efforts with live patients because of the potentially serious consequences of error.*

In contrast to diffuse damage, *focal brain lesions* are circumscribed areas of abnormal change in brain structure, such as might occur with traumatic injury to a part of the head. With progressive brain disease, such as Alzheimer's disease or expanding brain tumors, one may see a gradual spreading over more and more focal sites, leading to permanent damage that is both diffuse and severe. Some consequences of organic brain disorders that have mainly focal origins but commonly appear in the context of progressively diffuse damage are as follows:

1. *Impairment of memory*—the individual has notable trouble remembering recent events and less trouble remembering events of the remote past, with a tendency in some patients to confabulate; that is, to "invent" memories to fill in gaps. In severe instances no new experience can be retained for more than a few minutes. It either fails entirely to be stored in long-term memory or is stored in a way that provides no means for it to be readily retrieved at a later time.

2. *Impairment of orientation*—the individual is unable to locate himself or herself accurately, especially in time but also in space or in relation to the personal identities of self or others.

3. *Impairment of learning, comprehension, and judgment*—the individual displays ideation tending to be concrete and impoverished and is unable to think on higher conceptual levels or to plan with foresight.

4. *Impairment of emotional control or modulation*—the individual manifests emotional overreactivity and easy arousal to laughter, tears, rage, and other extreme emotions.

5. *Apathy or emotional blunting*—the individual shows little emotion, especially where deterioration is advanced.

6. *Impairment in the initiation of behavior*—the individual lacks "self-starting" capability and may have to be repeatedly reminded about what to do next, even where the behavior involved remains well within the person's range of competence.

7. *Impairment of controls over matters of propriety and ethical conduct*—the individual may manifest a marked lowering of personal standards in appearance, personal hygiene, sexuality, language, and so on.

8. *Impairment of receptive and expressive language*—the individual may be unable to comprehend written or spoken language, or may be unable to communicate thoughts orally or in writing.

9. *Impaired visuospatial ability*—the individual has difficulty in coordinating motor activity with the characteristics of the visual environment, affecting performance in graphomotor (handwriting and drawing), constructional (e.g., assembling things), and other tasks dependent on such skills.

**The Neuropsychology/Psychopathology Interaction** Most people who have a neuropsychological disorder do not develop psychopathological symptoms, such as panic attacks, dissociative episodes, or delusions, although many will show at least mild deficits in cognitive processing and self-regulation. The psychopathological symptoms that do sometimes accompany brain impairment are less predictable than those just listed and more likely to show individual nuances consistent with the prior personality and the total psychological situation confronting the patient. We consider it important for reasons of clarity to try to maintain a sharp distinction *conceptually* between neurological (or neuropsychological) and psychopathological types of "mental" symptoms.

In general, then, we are concerned here with people who have both neurological disease and psychopathological disorder. Though the distinction between these differing types of disorders is reasonably clear in the abstract, it becomes murky in many cases as psychopathology and neuropathology can become inextricably enmeshed with one another. We emphasize again that it is erroneous to assume that a psychological disorder, for example, a serious depression accompanying deficits produced by brain injury, is necessarily and completely explained by reference to the patient's brain damage; it might better be explained in terms of the psychological challenge presented by the patient's awareness of dramatically lessened competence.

The variable effects of significant impairment on individuals are explained by the fact that an individual is a functional unit and reacts as such to all stressors, whether they are organic or psychological. A well-integrated personality can usually withstand brain damage (or any other stress) better than a rigid, immature, or otherwise psychologically handicapped one—except where brain damage is so severe or its location so critical as to destroy the integrity of the personality. Similarly, an individual who has a favorable life situation is likely to have a better prognosis than one who does not. Because the brain is the center for the integration of behavior, however, there are limits to the amount of brain damage that anyone can tolerate or compensate for without exhibiting behavior that is decidedly abnormal.

**Hardware and Software** We believe that it is somewhat hazardous to employ computer analogies in discussions of the brain and mental processes. However, such an analogy seems to be useful in the context of the present discussion of the relationship of brain impairment to behavioral abnormalities.

When computers fail to do what we want and expect them to do for us, our troubleshooting speculations normally begin with two possibilities: (a) a hardware problem—perhaps a "sticky" chip, a deficient power supply, or a defective resistor or capacitator; or (b) a software problem, such as having a "bug" in our program of procedural instructions or an error in the data we load into a machine that is in perfect working order. Note that the software programs and data we load into computers have an essentially symbolic, informational status that is prior to and independent of the physical characteristics of the machine itself, although the physical state of the machine is transformed by the act of loading information into it. The information in a loaded machine could, in principle and with great difficulty, be completely and errorlessly reconstructed from a detailed description of the physical state of the machine. The two cannot for that reason be considered identical entities, however, nor is it reasonable to hold that the state of the machine is in any sense more "basic" than the information loaded into it.

We may thus consider the intact human brain to be a highly programmable system of hardware, and psychosocial experience in both its developmental and current aspects to be functionally equivalent to software. Using our analogy, neuropsychological disorders by definition have hardware defects as their primary cause. In other words, in such situations the brain cannot perform the physical operations called for by virtue of a breakdown in one or another (or several) of its components. The direct "symptoms" of such a breakdown should be, within reason, predictable from a knowledge of how these components "work."

A breakdown in the brain's hardware will necessarily have pervasive effects on the processing of software, or past and present experience. Indeed, in the case of extensive hardware damage, much or perhaps most previously loaded information may be lost because the structural components in which it had been encoded are no longer operative; new information for the same reason fails to be adequately loaded. Such a condition is known clinically as *dementia*. With less extensive hardware damage, we see effects that depend to a considerable extent on the particular characteristics of the software that constitutes the record of an individual's life experience, which is unique. We thus expect to see more variation in the "mental" symptoms manifested. To use an obvious example, the delusion that one is Napoleon, rather common in the nineteenth century, would not have been seen in an eighteenth-century demented patient who lived before Napoleon became famous. Such symptoms are at most only indirect manifestations of organic hardware breakdown; their content is obviously a product of life experience, and they sometimes occur in the absence of any demonstrable hardware breakdown at all. In this case, we must consider the possibility that they are due entirely to serious flaws in the individual's personality, or (in our analogy) software.

It is obvious that people vary a great deal in the adequacy, complexity, and resourcefulness of the software programs their experiences have provided. Indeed, as we will see later in this chapter, such variations are to a certain extent what IQ tests attempt to measure. It is equally obvious that few people have programs ready to compensate for the loss of basic competencies and skills that have become so automatized that their flawless performance requires no deliberate attention or effort. Coping with such loss puts a premium on the adaptive flexibility of a person's existing software library. *Failure* to cope adequately, on the other hand, places an additional load of stress and frustration on an already limited system, one that may be further compromised by newly acquired hardware defects. Such a system, we suggest, is likely to develop indirect, secondary psychopathological symptoms, such as the delusional assumption of a new and more impressive personal identity.

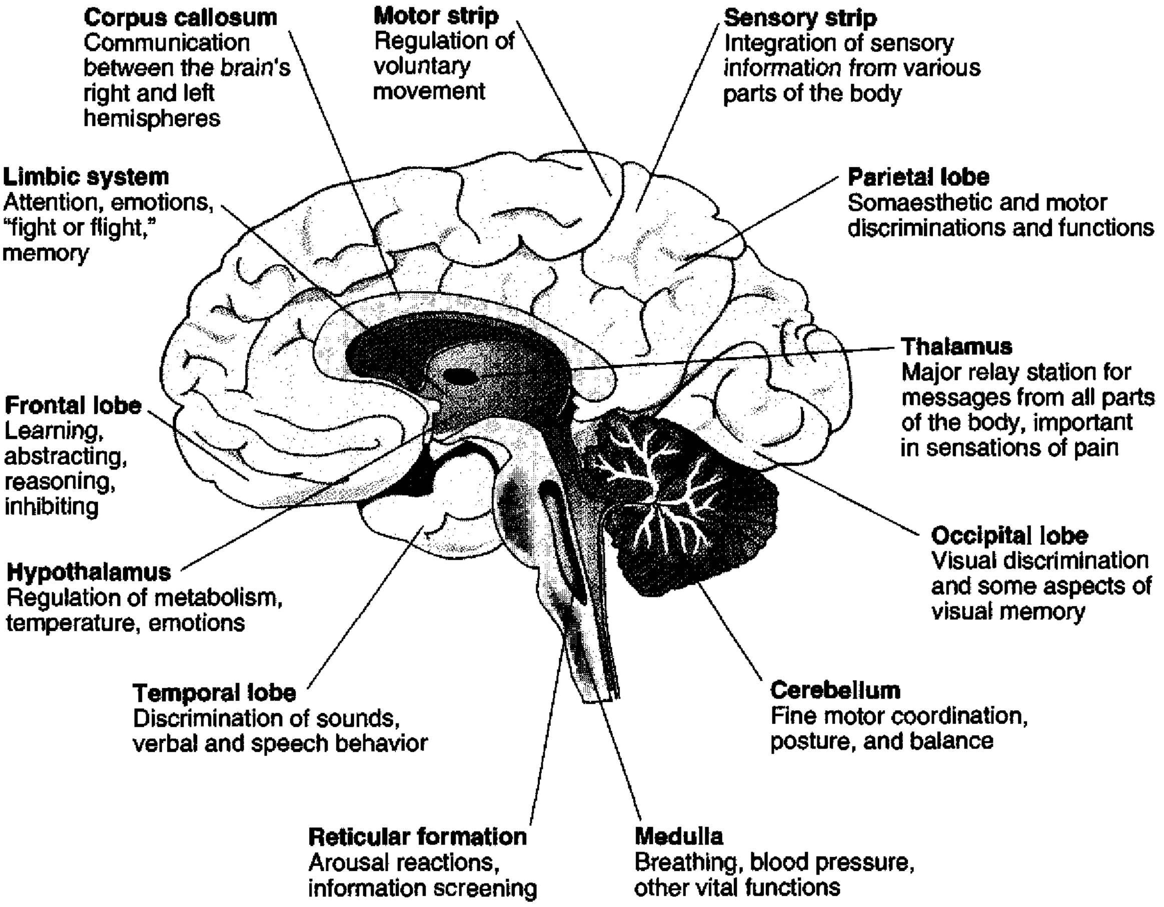
**General Clinical Features of Neuropsychological Disorders** The regenerative capacities of the central nervous system are limited. Although recovery of function following brain injury is often quite rapid, much of this is due to the resolution of temporary conditions, such as edema (swelling), produced in tissue spared from actual damage. With possibly minor exceptions, cell bodies and neural pathways in the brain do not have the power of regeneration, which means that their destruction is permanent. Some functions lost as a result of actual brain damage may be relearned, typically at a compromised and less efficient level, or the injured person may develop techniques to compensate for what is missing. Recovery from disabilities following an irreversible brain lesion may be relatively complete or limited, and it may proceed rapidly or slowly. Because there are limits to both the plasticity and compensatory capacities of the brain, however, brain damage leads to more or less extensive permanent diminishment or loss of function over a wide range of physical and psychological abilities. In general, as already noted, the greater the amount of tissue damage, the greater the impairment of function.

The location of the damage may also play a significant role in determining a patient's ultimate neuropsychological status. The brain is highly specialized, each part—each cell in fact—making a unique contribution to the functional whole of an organ-

13.1

## Implications of Brain Damage

It is difficult to predict the effects of focal injuries to the brain. Because there is some localization of function (as indicated in this drawing of the right cerebral hemisphere), damage to a particular area may cause impairment of the behavioral functioning mediated by the site of the damage. For example, a significant lesion of the occipital lobe is likely to result in some impairment of vision or visual perception. However, the awesome complexity of the brain's organization ensures that virtually all behavior is in fact the product of neuronal activity in many parts of the brain, some in all probability quite distant from the site of primary mediation. A lesion in one of the frontal lobes, for example, might influence neuronal activity at a site in the subcortical limbic system, thus producing some type of emotional dysregulation for the person affected. The result is that brain-behavior relationships are never as simple as graphic brain localization charts (such as this one) make them appear to be.



**Corpus callosum** Communication between the brain's right and left hemispheres
**Motor strip** Regulation of voluntary movement
**Sensory strip** Integration of sensory information from various parts of the body
**Limbic system** Attention, emotions, "fight or flight," memory
**Parietal lobe** Somaesthetic and motor discriminations and functions
**Thalamus** Major relay station for messages from all parts of the body, important in sensations of pain
**Frontal lobe** Learning, abstracting, reasoning, inhibiting
**Occipital lobe** Visual discrimination and some aspects of visual memory
**Hypothalamus** Regulation of metabolism, temperature, emotions
**Temporal lobe** Discrimination of sounds, verbal and speech behavior
**Cerebellum** Fine motor coordination, posture, and balance
**Reticular formation** Arousal reactions, information screening
**Medulla** Breathing, blood pressure, other vital functions

ism's activity (see HIGHLIGHT 13.1). Thus the two hemispheres, while interacting intimately at many levels, are involved in somewhat different types of mental processing. For example, functions that are dependent on serial processing of familiar information, such as language, take place mostly in the left hemisphere for nearly everyone. The right hemisphere is generally specialized for configurational or *gestalt* processing, which is best suited for grasping overall meanings in novel situations, reasoning on a nonverbal, intuitive level, and appreciation of spatial relations. Even within hemispheres, the various lobes and areas within lobes mediate somewhat specialized functions.

Although none of these relationships between brain location and behavior can be considered constant or universal, it is possible to make broad generalizations about the likely effects of damage to particular parts of the brain. Damage to the frontal areas, for example, is associated with either of two contrasting clinical pictures: (a) behavioral inertia, passivity, apathy, and an inability to give up a given stream of associations or initiate a new one (perseverative thought); or (b) impulsiveness, distractibility, and insufficient ethical restraint. Damage to specific areas of the right parietal lobe may produce impairment of visual-motor coordination or distortions of body image, while damage to the left parietal may impair certain aspects of language function, including reading and writing, as well as arithmetical abilities.

Damage to identified structures within the temporal lobes disrupts an early stage of memory storage, such that extensive bilateral temporal damage can produce a syndrome in which remote memory remains relatively intact but nothing new can be effectively stored for later retrieval. Damage to other structures within the temporal lobes is associated with disturbances of eating, sexuality, and the emotions, probably by way of disrupting the functioning of the adjacent limbic lobe. The latter is a deeper center that mediates these "primitive" functions in extensive interaction with frontal-lobe structures. Occipital damage produces a variety of visual impairments and visual association deficits, the nature of the deficit depending on the particular site of the lesion. For example, a person may be unable to recognize familiar faces or to visualize and understand symbolic stimuli correctly. Unfortunately, many types of brain disease are general and diffuse in their destructive effects, thereby causing multiple and widespread interruptions of the brain's circuitry.

**Diagnostic Issues in Neuropsychological Disorders** The DSM-IV manages the diagnostic coding of various neuropsychological disorders in different and somewhat inconsistent ways. Traditionally, these disorders have been classified by disease entity or recognizable medical disorder, such as Huntington's disease, general paresis, and so on. That is, the principal etiologic factor, the underlying neurological disease process, was specified in the diagnostic term applied. As we have seen, however, such basically medical disorders that may have various kinds of associated mental symptoms are normally coded not on Axis I but on Axis III of the DSM-IV. The associated *mental* conditions are then typically coded on Axis I, normally with the qualifying phrase, "Due to [a specified General Medical Condition]" (i.e., the disease process indicated on Axis III). Many of the common neuropsychological disorders are handled in this manner, but there are important exceptions, as noted below.

Some pathologic brain changes that may produce significant mental symptoms are related to the pathogenic effects of abusing certain substances, such as long-term, excessive alcohol consumption (see Chapter 10). In these cases a specific etiologic notation is included in the Axis I diagnosis, as in "Substance-Induced Persisting Amnestic Disorder" (referring to a circumscribed and characteristic type of memory impairment). DSM-IV also deals in a special way with certain conditions, often progressive, that result in pronounced and generalized cognitive deterioration, or ***dementia***. Here the presumed underlying neurological disease process is sometimes included in the Axis I designation, and also on Axis III as well. Thus, notable cognitive impairment associated with cerebrovascular disease might have a DSM-IV diagnostic code as follows:

*Axis I: Vascular Dementia*

*Axis III: Occlusion, cerebral artery*

Bearing in mind these basic and potentially confusing issues concerning relationships between the brain, mental contents and processes, behavior, and formal diagnosis, we move now to a consideration of several of the more common and important neuropsychological clinical syndromes.

## Neuropsychological Symptom Syndromes

As we have seen, a syndrome is a group of symptoms that tend to cluster together. The neuropsychological syndromes include many symptoms similar to those that occur in the schizophrenias, the mood disorders, and certain Axis II personality disorders, but in these syndromes the symptoms are assumed to reflect underlying brain pathology. The specific brain pathology may vary; it may be the result of brain disease or of the withdrawal of a chemical substance on which a person has become physiologically dependent. For our purposes, we will group these symptom syndromes into four categories: (a) delirium and dementia; (b) amnestic syndrome; (c) neuropsychological delusional and mood syndromes; and (d) neuropsychological personality syndromes.

We should note that more than one syndrome may be present at a time in a given patient and that syndromes and patterns of syndromes may change over a particular disorder's course of development.

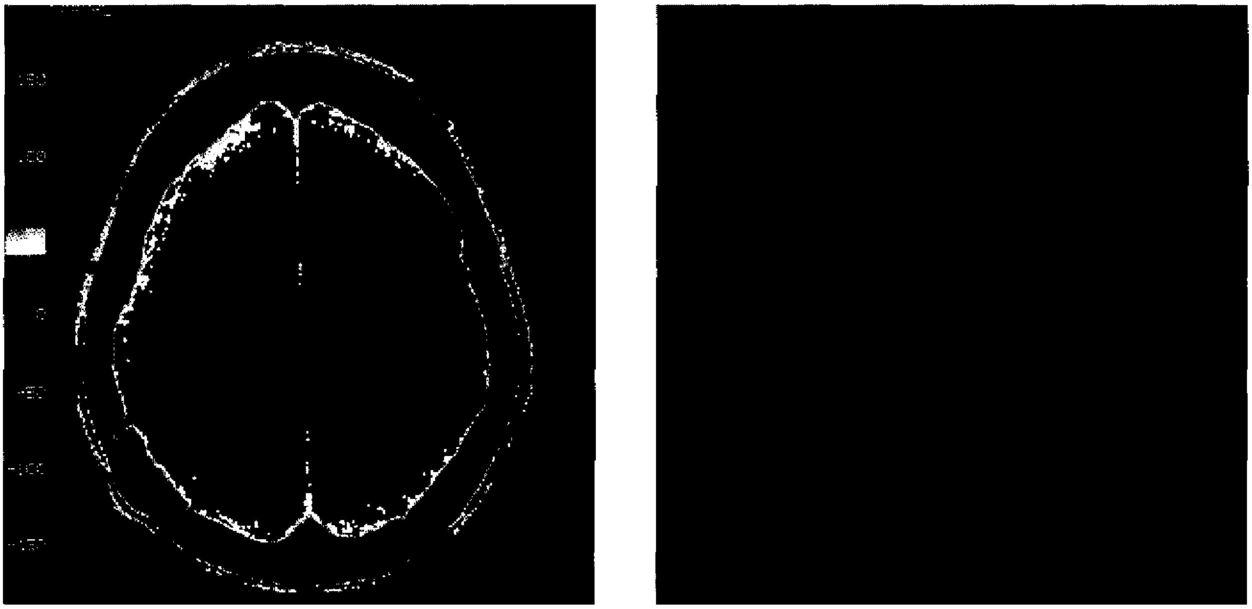
As already noted, some syndromes mimic at the behavioral level the types of disorders we have described in previous chapters. Although we suspect these are often basically the same types of (primarily psychogenic) disorders as those discussed earlier, clinicians always need to be alert to the possibility that brain impairment may be responsible for the symptoms observed. Failure to do so could obviously result in serious diagnostic errors (Geschwind, 1975; Malamud, 1975; Weinberger, 1984).

**Delirium and Dementia** The syndrome called **delirium** is characterized by the relatively rapid onset of widespread disorganization of the higher mental processes; it is caused by a generalized disturbance in brain metabolism. Information-processing capacities are impaired, affecting such basic functions as attention, perception, memory, and thinking; and the patient may have frightening hallucinations. The syndrome often includes abnormal psychomotor activity, such as wild thrashing about, and disturbance of the sleep cycle. Delirium reflects a breakdown in the functional integrity of the brain. In this respect, it may be seen as only one step above coma and, in fact, it may lead to coma. A delirious person is essentially unable to carry out purposeful mental activity of any kind; current experience appears to make no contact with the person's previously acquired store of knowledge.

Delirious states tend to be acute conditions that rarely last more than a week, terminating in recovery or, less often, in death due to the underlying injury or disease. Delirium may result from several conditions, including head injury, toxic or metabolic disturbances, oxygen deprivation, insufficient delivery of blood to brain tissues, or precipitous withdrawal from alcohol or other drugs in an addicted person.

**Dementia,** already mentioned, has as its essential feature a normally progressive deterioration of brain functioning occurring after the completion of brain maturation (after, that is, about 15 years of age). Early in the course of the disease, an individual is alert and fairly well attuned to events in the environment. Episodic (memory for events), but not necessarily semantic (language and concept), memory functioning is typically affected in the early stages, especially memory for recent events. Patients with dementia also show increasingly marked deficits in abstract thinking, the acquisition of new knowledge or skills, visuospatial comprehension, motor control, problem solving, and judgment. Personality deterioration and loss of motivation accompany these other deficits. Normally, dementia is also accompanied by an impairment in emotional control and in moral and ethical sensibilities. It may be progressive or static; occasionally it is even reversible. Its course depends to a large extent on the nature of the etiology.

Etiologic factors in dementia are many and varied. They include degenerative processes that usually, but not always, affect older individuals. Other causes may be repeated cerebrovascular accidents (strokes); certain infectious diseases, such as syphilis,



*Dramatic differences show up in these CAT scans of a normal brain (left) and the brain of a person afflicted with probable Alzheimer's dementia (right). The dark blue areas in both hemispheres of the diseased brain indicate an enlargement of the ventricles (the large, hollow spaces deep within the brain) due to the degeneration of the brain tissue.*

13.2

## Dementia in 417 Patients Fully Evaluated for Dementia

| Diagnosis | Number | Percent |
|---|---|---|
| Alzheimer's disease or dementia of unknown cause | 199 | 47.7 |
| Alcoholic dementia | 42 | 10.0 |
| Multi-infarct dementia [VAD] | 39 | 9.4 |
| Normal pressure hydrocephalus | 25 | 6.0 |
| Intracranial masses [tumors] | 20 | 4.8 |
| Huntington's disease | 12 | 2.9 |
| Drug toxicity | 10 | 2.4 |
| Posttraumatic | 7 | 1.7 |
| Other identified dementing diseases[a] | 28 | 6.7 |
| Pseudodementias[b] | 28 | 6.7 |
| Dementia uncertain | 7 | 1.7 |

[a] Including epilepsy, subarachnoid hemorrhage, encephalitis, amyotropic lateral sclerosis, Parkinson's disease, hyperthyroidism, syphilis, liver disease, and cerebral anoxia episode, all less than 1 percent incidence.

[b] Including depression (16), schizophrenia (5), mania (2), "hysteria" (1), and not demented (4).

Based on Wells (1979).

meningitis, and AIDS; intracranial tumors and abscesses; certain dietary deficiencies; severe or repeated head injury; anoxia (lack of oxygen); and the ingestion or inhalation of toxic substances. As HIGHLIGHT 13.2 makes clear, the most common cause of dementia is degenerative brain disease, particularly Alzheimer's disease.

**The Amnestic Syndrome** The essential feature of the **amnestic syndrome** is a striking deficit in the ability to recall ongoing events more than a few minutes after they have taken place. Immediate memory and, to a lesser extent, memory for events that occurred before the disorder's development remain largely intact, as does memory for words and concepts. An amnestic individual, then, is constrained to live for the most part only in the present or the remote past; the recent past is for most practical purposes unavailable. We should add here that the question of whether the recent past is unavailable in some absolute sense is subject to differing interpretations. Some evidence suggests that these individuals may recognize or even recollect events of the recent past if given sufficient cues, which would indicate that the information has been stored. Thus the difficulty may be in the retrieval mechanism (Hirst, 1982; Warrington & Weiskrantz, 1973).

In contrast to the dementia syndrome, overall cognitive functioning in the amnestic syndrome remains relatively intact. Theoretically, the disorder involves chiefly the relationship between the short-term and long-term memory systems; the contents of the former, always limited in scope and ephemeral in duration, are not stored in the latter in a way that permits ready accessibility or retrieval (Hirst, 1982).

In the most common forms of amnestic syndrome, those associated with alcohol or barbiturate addiction, the disorder may be irreversible. A wide range of other pathogenic factors may produce the amnestic syndrome. In these cases, depending on the nature and extent of damage to the affected neural structures and on the treatment undertaken, the syndrome may in time abate wholly, in part, or not at all.

**Neuropsychological Delusional and Mood Syndromes** In this type of delusional syndrome, false beliefs or belief systems arise in a setting of known or suspected brain impairment and are considered a principal clinical manifestation of this organic pathology. These delusions vary in content depending to some extent on the particular etiology. For example, a distinctly paranoid and suspicious delusional system is commonly seen with long-standing abuse of amphetamine drugs, whereas grandiose and expansive delusions are more characteristic of advanced neurosyphilis (general paresis). In addition to infectious processes and the abuse of certain drugs, etiological factors in the neuropsychological delusional syndrome include head injury and intracranial tumors.

Some cases of serious mood disturbance appear to be caused by disruptions in the normal physiology of cerebral function. Such conditions may closely resemble the symptoms seen in either depressive or manic mood disorders. Severe depressive syndromes, whether or not associated with organic pathology, may on superficial examination appear as dementias, in which case the term *pseudodementia* is often applied. The reaction may be minimal or severe, and the course of the disorder varies widely, depending on the nature of the organic pathology. Etiological factors include cerebrovascular accidents (strokes), Parkinson's disease, head injury, withdrawal of certain drugs, intracranial tumors or tumors of the hormone-secreting organs, and excessive use of steroid (adrenocortical hormone) drugs or certain other medications. Of course, an awareness of lost function or a hopeless outlook might itself make a person depressed, thus indicating a need for special care in the diagnostic process when there is reason to believe the patient harbors pessimistic thoughts about his or her clinical outcome (see Teri & Wagner, 1992).

*This man has Parkinson's disease, which may be associated with a neuropsychological mood syndrome, a cluster of symptoms that closely resembles those seen in either depressive or manic mood disorders.*

**Neuropsychological Personality Syndromes** The essential feature of these syndromes is a change in an individual's general personality style or traits following brain impairment. Normally the change is in a socially negative direction; it may include impaired social judgment, lessened control of emotions and impulses, diminished concern about the consequences of one's behavior, and an inability to sustain goal-directed activity. Many different etiologies are associated with the neuropsychological personality syndromes, and the course of the disorder depends on its etiology. Occasionally, as when it is induced by medication, it may be transitory. Often, however, it is the first sign of impending deterioration, as when a kindly and gentle old man makes sexual advances toward a child or when a conservative executive suddenly begins to engage in unwise financial dealings. Some evidence indicates that a common feature in the organic personality syndrome may be damage to the frontal lobes (Crockett, Clark, & Klonoff, 1981; Sherwin & Geschwind, 1978; Stuss, Gow, & Heatherington, 1992), perhaps especially the *right* frontal (Borod, 1992).

The DSM-IV classification lists several different mental disorders in which brain impairment or other "general medical conditions" are believed to be contributory; many of these are related to drug abuse and involve only temporary physiological disruption (see Chapter 10). The disorders we will discuss in the following sections are longer-term disorders in which major, usually permanent, brain pathology occurs but in which an individual's emotional, motivational, and behavioral reactions to the loss of function also play an important role. Indeed, as was earlier suggested, it is often impossible to distinguish between maladaptive behavior that is directly caused by neuropsychological dysfunction and that which is basically part of an individual's psychological reaction to the deficits and disabilities experienced (Fabrega, 1981; Geschwind, 1975; Teri & Wagner, 1992).

The three types of neuropsychological mental disorder we will discuss in greater detail are HIV-1 infection of the brain, dementia of the Alzheimer's type, and disorders involving traumatic head injury. Vascular (formerly multi-infarct) dementia will be briefly addressed in the section on Alzheimer's, chiefly as a contrast to that disease.

## Neuropsychological Disorder with HIV-1 Infection

Our discussion of mental disorder associated with the HIV-1 virus will necessarily be rather brief because these problems are relatively newly recognized ones. As we saw in Chapter 8, the devastating effects on the immune system produced by infection with the HIV Type 1 virus renders its victims "opportunistically" susceptible to a wide variety of other infectious agents. When neuropsychological syndromes were first observed among AIDS patients early in the last decade, it was assumed that they were due to secondary infections of this sort or to the brain tumors also associated with immune system incompetence. Then, in 1983, Snider and colleagues published the first systematic evidence that the presence of the HIV-1 virus (or a mutant form of it) could itself result in the destruction of brain cells. Since then, several different forms of such HIV-induced central nervous system pathology have been identified, some of which appear to be associated with the emergence of psychotic (e.g., delusional) phenomena (Sewell et al., 1994). To date, however, most attention has focused on the **AIDS dementia complex (ADC)**, a generalized loss of cognitive functioning affecting a substantial proportion of AIDS patients.

The neuropathology of ADC involves various changes in the brain, among them generalized atrophy, edema, inflammatory cells, and patches of demyelination (loss of the myelin sheath surrounding nerve fibers), as described by various investigators (Gabuzda & Hirsch, 1987; Gray, Gherardi, & Scaravilli, 1988; Price et al. 1988a; Sewell et al., 1994). No brain area may be spared, but the damage appears concentrated in subcortical regions, notably the central white matter, the tissue surrounding the ventricles, and deeper gray matter structures such as the basal ganglia and thalamus.

Clinical features, which tend to appear as a late phase of HIV infection (although often before the full development of AIDS itself), usually begin with psychomotor slowing, diminished concentration, mild memory difficulties, and perhaps slight motor clumsiness. Progression is typically rapid after this point, with clear-cut dementia appearing in many cases within one year, although considerably longer periods have been reported. The later phases of ADC can be quite grim and include behavioral regression, confusion, psychotic thinking, apathy, and marked withdrawal, leading before death to an incontinent, bedridden state (Navia, Jordan, & Price, 1986; Price et al., 1988a, 1988b).

As many as 80 percent of patients with full-blown AIDS have neuropathological findings at autopsy (Petito, 1988). Thirty-eight percent of 121 living AIDS patients studied by Navia and colleagues (1986) met DSM criteria for dementia. Patients with **AIDS-related complex (ARC)**, a pre-AIDS manifestation of HIV infection involving minor infections, various nonspecific symptoms (such as unexplained fever), and blood cell count abnormalities, may also experience cognitive difficulty, although it may be too subtle to be readily detected on clinical observation alone. In one study (Grant et al., 1987), 54 percent of ARC patients demonstrated definite impairment on a neuropsychological test battery. Other studies, reviewed by Grant and Heaton (1990), have shown inconsistent evidence of neuropsychological compromise in pre-ARC people who are merely infected with the HIV-1 virus. Significant numbers of infected persons were also found to be neuropsychologically compromised in a cross-national study recently reported by Maj and colleagues (1994), although these investigators emphasize the subtlety of the deficits detected and their lack of substantial impact on social functioning in otherwise asymptomatic persons. Depression, a frequent accompaniment of HIV infection, does not appear to account for the compromised neuropsychological test performance observed in these patients (Beason-Hazen, Nasrallah, & Bornstein, 1994).

The overall evidence is thus compelling that infection with the HIV-1 virus poses a substantial threat to the anatomical integrity of the brain, quite apart from its other frightening characteristics. As of this writing, it is not known what protects the minority of AIDS patients who show no central nervous system involvement during the entire course of their illnesses.

The question of treatment for ADC is of course intimately tied to that involving control or eradication of the HIV-1 infection itself. Until recently, it was impossible to feel confident about our prospects because of the enormous and unprecedented challenges presented by the complex structure and life cycle of this virus (McCutchan, 1990). This picture may be improving with advances in antiviral therapy. For example, Sidtis, Gatsonis, and Price (1993) have recently reported apparent arrest and in some instances even reversal of ADC progression among many persons treated with zidovudine (AZT); unfortunately, experience with AZT therapy in the more general AIDS context indicates that this effect will probably prove temporary because the virus adapts over time to the presence of AZT. It remains true therefore that prevention of infection is the only certain defensive strategy, a circumstance not unlike the problem posed by neurosyphilis, another sexually transmitted and potentially dementing disease, in an earlier era. In general, humankind has not done well in controlling the spread of sexually transmitted diseases through cautious sexual behavior, and, as was noted in Chapter 8, that pattern seems to be repeating itself with respect to the HIV-1 virus.

## Dementia of the Alzheimer's Type

While the dementia complicating many cases of HIV-1 infection is a very serious concern, especially for the family and friends of victims, it is dwarfed in magnitude by the problems our society faces in coping with the dementias that are the most salient aspect of Alzheimer's disease, officially (as on Axis I of DSM-IV) termed **Dementia of the Alzheimer's Type (DAT).** DAT takes its name from Alois Alzheimer, a German neuropsychiatrist, who first described it in 1907.

It is a commonplace observation that the organs of the body deteriorate with aging. The cause or causes of this deterioration, however, remain largely obscure; science has not yet solved the riddle of aging. Of course, the brain—truly the master organ—is not spared in the aging process. Over time it too wears out, or degenerates. Mental disorders that sometimes accompany this brain degeneration and occur in old age have traditionally been called **senile dementias.** Unfortunately, a number of rare conditions result in degenerative changes in brain tissue earlier in life. Disorders associated with such earlier degeneration of the brain are known as **presenile dementias.**

Not only is the age of onset different in the presenile dementias, but they are also distinguished from the senile dementias by their different behavioral manifestations and brain tissue alterations (see HIGHLIGHT 13.3). One important exception is Alzheimer's disease, which is a typical and common senile disorder but which can, in some people, occur well before old age. Alzheimer's disease is associated with a characteristic dementia syndrome having an insidious onset and a usually slow but progressively deteriorating course, terminating in death.

The DAT diagnosis is normally rendered only after all other potential causes of dementia are ruled out by case history, physical examination, and laboratory tests. As earlier noted, the parallel *medical* diagnosis, Alzheimer's disease, is coded on Axis III, although it is usually not possible to establish definitely the presence of the distinctive Alzheimer neuropathology (described below) in living patients. Brain imaging techniques, such as that of magnetic resonance imaging (MRI), may provide supportive evidence in showing enlarged ventricles or widening in the folds (sulci) of the cerebral cortex, indicating brain atrophy. Nevertheless, the use of antemortem (before death) criteria for the diagnosis of DAT is somewhat imprecise (Carlsson, 1986), with considerable possibility of overdiagnosing the condition (Hartford, 1986). In late 1994, a new and potentially quite accurate antemortem diagnostic test for Alzheimer's disease was announced (Scinto et al., reported by Pennisi, 1994), one involving an abnormal (excessive) response to a drug (tropicamide) that causes pupillary dilation when applied to the eye. This test may eventually enable accurate diagnosis in living patients.

When we picture a "typical" Alzheimer patient, we imagine a person of advanced age. Although most patients are older, for some, DAT is a presenile dementia that begins in their 40s or 50s; in such cases the progress of the disease and its associated dementia is often rapid. For example, in one study of early-onset DAT (Heyman et al., 1987) the five-year cumulative mortality rate was 2.5 times the expected rate, with the younger of these patients contributing disproportionately to the excess in deaths. Considerable evidence suggests an especially substantial genetic contribution in early-onset DAT (Davies, 1986), although different genes may well be involved in different families (Breitner et al., 1993). These early-onset cases, occurring in comparatively young and vigorous patients, portray the tragedy of Alzheimer's disease in an especially stark light.

In fact no way exists to portray the ravages of this disorder in other than an alarming fashion, even if we restrict attention to the more typical instance of onset after age 65. Survival to at least that point is becoming increasingly routine, and after the first decade of the twenty-first century, the first members of the enormous post–World War II baby boom generation will enter the age range of maximum risk. If we have not solved the problem of curing or preventing DAT by that time or shortly thereafter, the social and economic consequences will clearly be devastating (Fisher & Carstensen, 1990).

Nor is there any real assurance, despite our rapidly advancing knowledge about the disorder, that a solution will be found. Just as people do not die of old age per se but rather of failing organs, there is no cure or preventive measure for the aging of living organisms. Some investigators, for example, Selkoe (1986), suggest that Alzheimer's "disease" is merely the product of the aging process as manifested in a particular organ, the brain. Early onset is early brain aging, probably for the most part genetically determined. Prevention or cure, according to this view, would therefore approximate in its unlikelihood the discovery of the Fountain of Youth. Somewhat reassuringly, other researchers, Comfort (1984) and Glenner (1986), for example, reject this

13.3

## Presenile Dementias

In addition to early-occurring Alzheimer's disease, two other forms of presenile dementia occur with sufficient frequency to deserve mention: Pick's disease and Huntington's disease.

**Pick's Disease**

Even rarer than early-onset Alzheimer's disease, Pick's disease (first described by Arnold Pick of Prague in 1892) is a degenerative disorder of the brain, usually having its onset in people between the ages of 45 and 50. Its cause is unknown. Women are apparently more subject to Pick's disease than men, at a ratio of about three to two. Onset is slow and insidious, involving difficulty in thinking, slight memory defects, easy fatigability, and, often, character changes with a lowering of many social inhibitions. At first there is a circumscribed atrophy of the frontal and temporal lobes; as the atrophy becomes more severe, the mental deterioration becomes progressively greater and includes apathy and disorientation as well as the impairment of judgment and other intellectual functions. The disease usually runs a fatal course within two to seven years.

**Huntington's Disease**

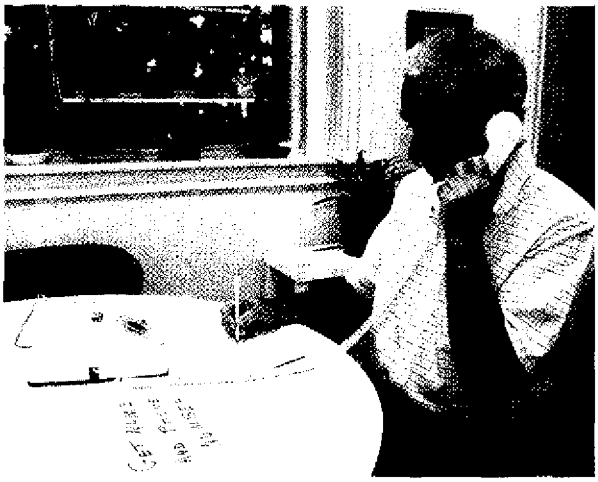
Huntington's disease is a genetically determined (autosomal dominant) degenerative disorder of the central nervous system. It was first described by the American neurologist George Huntington in 1872. With an incidence rate of about 5 cases per 100,000 people, the disease usually occurs in individuals between 30 and 50 years of age. Behavior deterioration often becomes apparent several years before there are any detectable neurological manifestations (Lyle & Gottesman, 1977). The disease itself is characterized by a chronic, progressive chorea (involuntary and irregular twitching, jerking movements) with mental deterioration leading to dementia and death within 10 to 20 years. Although Huntington's disease cannot be cured or even arrested at the present time, it can be prevented, at least in theory, by genetic counseling, because its occurrence is a function of known genetic laws.

notion and hold that DAT is a specific disease process, hence in principle both preventable and curable.

Yet a third, and intermediate, view of the problem is offered by Gatz and colleagues (1994), who note that many eventually fatal organ system failures, Alzheimer's disease among them, seem to be the product not of a single or even a limited array of specific causal factors. Rather, they are the result of an accumulation of risk factors that ultimately exceed some clinical threshold and produce disease. Advancing age, of course, increases risk exposure. This view leaves open the possibility of reducing or delaying the occurrence of DAT through deliberately limiting exposure to risks, some of which are clearly environmental or otherwise potentially controllable. Gatz and her colleagues mention a variety of likely candidates, such as reduced alcohol consumption, for preventive interventions of this type.

The magnitude of the problem of DAT—often seriously underestimated—is already straining societal and family resources, both economic (Max, 1993) and emotional (see below). As shown in the table of HIGHLIGHT 13.2, the disorder accounts for nearly 50 percent of all cases of dementia of whatever cause. The ratio is doubtless considerably higher for older people. It is estimated that one of every six people in the United States over age 65 is clinically demented, and that one of every ten people in this age range suffers from DAT (Evans et al., 1989). The prevalence rate of DAT may approach 50 percent by age 85 (Fisher & Carstensen, 1990), and a recent United Kingdom study indicates that, in each five-year interval from ages 75 to 89, there is an approximate doubling of the rate of new cases of DAT (Paykel et al., 1994). There are thus some 4 million living victims in the United States alone, and the number is increasing rapidly with the advancing age of the population. About 30 to 40 percent of nursing home residents are DAT patients (Kolata, 1981a). Some of these patients reside in mental hospitals or other types of institutional settings. Most, however, live in the community, typically with family members (Gurland & Cross, 1982), a circumstance that is often extremely stressful for caregivers (Brane, 1986; Fisher & Carstensen, 1990; Intrieri & Rapp, 1994).

**The Clinical Picture in DAT** As already noted, the onset of Alzheimer's disease in older people is usually gradual, involving slow mental deterioration. In some cases a physical ailment or some other stressful



*Written reminders can help Alzheimer's victims lead relatively normal lives. In the early stages, they can remember how to do things once they are reminded to do them. Later on, they may lose the ability to do even simple tasks.*

event is a dividing point, but usually an individual passes into a demented state almost imperceptibly, so that it is impossible to date the onset of the disorder precisely. The clinical picture may vary markedly from one person to another, depending on the nature and extent of brain degeneration, the premorbid personality of the individual, the particular stressors present, and the degree of environmental support.

Symptoms often begin with the person's gradual withdrawal from active engagement with life. There is a narrowing of social and other interests, a lessening of mental alertness and adaptability, and a lowering of tolerance to new ideas and changes in routine. Often thoughts and activities become self-centered and childlike, including a preoccupation with the bodily functions of eating, digestion, and excretion. As these changes—typical in a lesser degree of many older people—become more severe, additional symptoms, such as impaired memory for recent events, "empty" speech (in which grammar and syntax remain intact but vague expressions replace meaningful nouns and verbs), messiness, impaired judgment, agitation, and periods of confusion, make their appearance. Specific symptoms may vary considerably from patient to patient and from day to day for the same patient; thus the clinical picture is by no means uniform until the terminal stages, when the patient is reduced to a vegetative level. There is also, of course, individual variation in the rapidity of the disorder's progression. In rare instances the symptoms may reverse and partial function may return, but in true DAT this reversal will invariably prove temporary.

The end stages of Alzheimer's disease involve a depressingly similar pattern of reduction to a vegetative existence and ultimate death from some disease that overwhelms a person's limited defensive resources. Before this point, there is, as noted, some distinctiveness in patient behavior. Allowing for individual differences, a given victim is likely to show one of the several dominant behavioral manifestations described in the following paragraphs.

Approximately half of all DAT patients display a course of simple deterioration. That is, they gradually lose various mental capacities, typically beginning with memory for recent events and progressing to disorientation, poor judgment, neglect of personal hygiene, and loss of contact with reality to an extent precluding independent functioning as adults. Distinctly psychopathological symptoms (such as delusions), if they occur at all, are likely to be transitory and inconsistent over time. The following case—involving an engineer who had retired some seven years prior to his hospitalization—is typical of simple deterioration resulting from DAT:

> During the past five years, he had shown a progressive loss of interest in his surroundings and during the last year had become increasingly "childish." His wife and eldest son had brought him to the hospital because they felt they could no longer care for him in their home, particularly because of the grandchildren. They stated that he had become careless in his eating and other personal habits and was restless and prone to wandering about at night. He could not seem to remember anything that had happened during the day but was garrulous concerning events of his childhood and middle years.
>
> After admission to the hospital, the patient seemed to deteriorate rapidly. He could rarely remember what had happened a few minutes before, although his memory for remote events of his childhood remained good. When he was visited by his wife and children, he mistook them for old friends, nor could he recall anything about the visit a few minutes after they had departed. The following brief conversation with the patient, which took place after he had been in the hospital for nine months and about three months before his death, shows his disorientation for time and person:
>
> Doctor: How are you today, Mr. ____?
>
> Patient: Oh . . . hello (looks at doctor in rather puzzled way as if trying to make out who he is).

Doctor: Do you know where you are now?

Patient: Why yes . . . I am at home. I must paint the house this summer. It has needed painting for a long time but it seems like I just keep putting it off.

Doctor: Can you tell me the day today?

Patient: Isn't today Sunday . . . why, yes, the children are coming over for dinner today. We always have dinner for the whole family on Sunday. My wife was here just a minute ago but I guess she has gone back into the kitchen.

In a less frequent manifestation of Alzheimer's disease, a person develops a decidedly paranoid orientation to the environment, becoming markedly suspicious and often convinced that others are engaged in various injurious plots and schemes. Uncooperativeness and verbal abuse are common accompaniments, making the task of caregiving significantly more stressful. In the early phases of this reaction pattern, the cognitive deficits characteristic of Alzheimer's disease (memory loss, disorientation) may not be prominent, perhaps enabling the person to be quite observant and even logical in building the "case" for others' threatening activities. Though themes of victimization predominate in this form of the disorder, also common is the so-called jealousy delusion in which the person persistently accuses his or her partner or spouse—who is often of advanced age and physically debilitated—of being sexually unfaithful. Family members may be accused of various foul deeds, such as poisoning the patient's food or plotting to steal the patient's funds. Fortunately, punitive retribution in the form of physical attacks on the "evildoers" is rare, but a combative pattern does occasionally occur, complicating the patient's management. The following case is fairly typical of the paranoid reaction type:

A woman of 74 had been referred to a hospital after the death of her husband because she had become uncooperative and was convinced that her relatives were trying to steal the insurance money her husband had left her. In the hospital, she complained that the other patients had joined together against her and were trying to steal her belongings. She frequently refused to eat, on the grounds that the food tasted funny and had probably been poisoned. She grew increasingly irritable and disoriented for time and person. She avidly scanned magazines in the ward reading room but could not remember anything she had looked at. The following conversation reveals some of her symptoms:

Doctor: Do you find that magazine interesting?

Patient: Why do you care? Can't you see I'm busy?

Doctor: Would you mind telling me something about what you are reading?

Patient: It's none of your business . . . I am reading about my relatives. They want me to die so that they can steal my money.

Doctor: Do you have any evidence of this?

Patient: Yes, plenty. They poison my food and they have turned the other women against me. They are all out to get my money. They even stole my sweater.

Doctor: Can you tell me what you had for breakfast?

Patient: . . . (Pause) I didn't eat breakfast . . . it was poisoned and I refused to eat it. They are all against me.

Paranoid orientations tend to develop in people who have been sensitive and suspicious. Existing personality tendencies are apparently intensified by degenerative brain changes and the stress accompanying advancing age.

Other patterns seen in Alzheimer patients are comparatively infrequent. Some patients are confused but amiable, usually showing marked memory impairment and a tendency to engage in seemingly pointless activities, such as hoarding useless objects or repetitively performing household tasks in a ritualized manner. Other patients become severely agitated, with or without an accompanying "hand-wringing" depression. Depressed Alzheimer patients tend to develop extremely morbid preoccupations and delusions, such as hypochondriacal ideas about having various horrible diseases, often seen as punishment for past sins. Suicide is a possibility in such cases should a patient be physically capable of carrying out the act.

In some cases, the progress of the disease is unusually rapid and a patient moves quickly into a state of incoherence verging on delirium. This mental clouding is frequently accompanied by marked agitation and unpredictable combativeness, severely trying the resources of caregivers. As we have seen, all Alzheimer patients who survive long enough eventually enter a stage of continuous delirium.

With appropriate treatment, which may include medication and the maintenance of a calm, reassuring, and unprovocative social milieu, many people with Alzheimer's disease show some symptom alleviation. In general, however, deterioration continues its downward course over a period of months or years. Eventually, patients become oblivious of their surroundings, bedridden, and reduced to a vegetative existence. Resistance to disease is lowered, and death usually results from pneumonia or some other infection.

**Causal Factors in DAT** The fundamental neuropathology of the Alzheimer's brain has been known for some time. Readily determined by microscopic examination of tissue specimens, it has three elements: (a) the widespread appearance of "senile plaques," small areas of dark-colored matter that are in part the debris of damaged nerve terminals; (b) the tangling of the normally regular patterning of neurofibrils (strandlike protein filaments) within neuronal cell bodies; and (c) the abnormal appearance of small holes in neuronal tissue, called granulovacuoles, which derive from cell degeneration. Absolute confirmation of the diagnosis of DAT at present rests on observation of these changes in tissue samples, which is why it can usually be accomplished only after a patient has died. When sufficiently numerous, these microscopic alterations of the brain's substance lead to generalized brain atrophy, which may be visualized in live patients by imaging techniques. Unfortunately from the diagnostic standpoint, such atrophy may occur with several other disease conditions as well, and even as a correlate of normal aging.

Another important alteration in DAT concerns the neurotransmitter acetylcholine (ACh), which is known to be important in the mediation of memory. While there is widespread destruction of neurons in DAT, particularly in a small area of the hippocampus (Adler, 1994), evidence suggests that among the earliest and most severely affected are a cluster of cell bodies located in the basal forebrain and involved in the release of ACh (Coyle, Price, & DeLong, 1983; Whitehouse et al., 1982). This observation and related ones (e.g., Wester et al., 1988) have given rise to the ACh depletion theory of DAT etiology. Although the evidence is not conclusive, the theory does integrate an impressive array of research data. For example, a temporary DAT-like syndrome may be produced in normal subjects who are given ACh-blocking drugs (Kopelman, 1986); the newly approved drug tacrine (Cognex), which increases available brain ACh, is temporarily helpful in improving cognitive function in some DAT patients (Whitehouse, 1993); and finally the promising new pupillary dilation diagnostic technique mentioned earlier appears to depend upon pharmacodynamic effects involving ACh (Scinto et al., reported in Pennisi, 1994).

*An electrode headset picks up signals from the brain of a 58-year-old woman, and a computer turns them into the brain map on the screen. Brain-mapping can detect the depletion of acetylcholine, which is thought to play a role in the production of Alzheimer's disease.*

If we make the reasonable assumption that ACh depletion plays at least some role in the production of DAT symptoms, there is still the question of what place it occupies in the presumed causal chain. What, for example, causes the degeneration of ACh-releasing cells? Several hypotheses purport to answer such questions, but none has so far gained a consensus acceptance.

Some investigators have taken the more direct approach of trying to discover the sources of the primary DAT lesions such as neurofibrillary tangles and senile plaques. The search has yielded a considerable amount of information concerning, in particular, the composition of the latter. These plaques contain cell debris, but their cores consist of a sticky protein substance, called beta amyloid, that also occurs in abnormal abundance in other parts of DAT patients' brains (see Gajdusek, 1986; Hardy et al., 1986; Kang et al., 1987). This finding may turn out to be extremely important in leading to an understanding of DAT, in part because it may serve as a bridge to certain exciting new discoveries relating to the genetics of DAT, as reported below.

We have already mentioned that early-onset DAT, in common with numerous other instances of early-onset disease, seems to have a prominent genetic component in its etiology. In one interesting study involving early onset, Nee (reported in Sargent, 1982b) traced the disease back eight generations in one family that immigrated to this continent in 1837. Of 531 family members, 53 were identified as suffering from the disease, even though those who lived to 65 without symptoms were considered free of it. Collateral findings of this NIMH project showed that the mean interval between the onset of symptoms and death was 6 years (although in one case it was 24), and that the age at onset ranged between 44 and 64 years. In fact, widespread evidence shows that a general vulnerability to the development of DAT, even in very late-onset cases, may be inherited (Breitner, 1986; Breitner et al., 1993; Davies, 1986; Mohs et al., 1987; Sturt, 1986).

Much of this evidence points to a genetic connection with Down syndrome (to be discussed later in the chapter), which is due to a trisomy (tripling) involving chromosome 21. Most people with Down syndrome who survive beyond about age 40 develop a DAT-like dementia (Bauer & Shea, 1986; Janicki & Dalton, 1993), with comparable neuropathological changes (Schapiro & Rapoport, 1987). Anomalies of chromosome 21 have also been implicated in DAT (e.g., Van Broeckhoven et al., 1987), although that is plainly not the only site of origin for genetic influences in the disorder (Breitner et al., 1993; Clark & Goate, 1993). Barnes (1987) reported evidence that the same regions of chromosome 21 are involved in both Down syndrome and DAT, and that one of the genes in this region contributes to the production of the amyloid protein figuring so prominently in the neuropathology of DAT. Hardy and colleagues (as reported by Marx, 1991) identified a gene mutation on chromosome 21 in a DAT-prone family, one that could be implicated in the release of beta amyloid.

Owing to this impressive record of gradually narrowing the field in the search for the primary etiology of DAT, conditions had become quite favorable by the early 1990s for the emergence of a major breakthrough that would tie together the strands of the etiologic picture. The beginnings of that breakthrough may have come with the discovery, largely by Duke University scientists, of the role of a blood protein, apolipoprotein-E (ApoE), in somehow enhancing the buildup of beta amyloid, which is associated with cell death. The Duke team's theory minimizes the causal role of amyloid, considering its excess accumulation an effect of processes involved in cell death, which they believe is caused by ApoE-induced neurofibrillary tangling (*Wall Street Journal*, Nov. 8, 1993, pp. B1, B2). Other investigators (e.g., Potter et al., reported in Pennisi, 1994), while accepting the probable importance of ApoE, have continued, with considerable success, to focus on the potential of this protein to facilitate amyloid deposits directly. The genetic tie-in actually concerns three genetically distinct forms of ApoE; the risk of developing late-onset DAT varies quite markedly with the type of ApoE inherited (*Duke University Dialogue*, June 10, 1994, pp. 6, 11).

Exciting as they are, however, these recent discoveries still do not account for all cases of DAT. Many people inheriting the most "risky" ApoE gene do not succumb to DAT, and some who do succumb to the disease have no such gene. Many findings suggest that nongenetic variables are importantly involved in the etiology of DAT (Henderson, 1986), as is perhaps most clearly demonstrated in the occurrence of substantial numbers of monozygotic twins discordant for the disease (Breitner et al., 1993). For example, both Nee and colleagues (1987) and Renvoize and colleagues (1986) have described monozygotic twins discordant for DAT, a circumstance that is most readily explained by some sort of critical environmental influence. Unfortunately, we have little solid information about environmental risk factors; most hypotheses advanced in this area involve environmental toxins, but there are also suggestions that a past history of head trauma or of alcohol abuse may be implicated (Gatz et al., 1994).

Recent progress in understanding DAT is impressive. Although there are still many loose ends to be tied together, and some that may remain resistant to our best efforts, the progress of the last 15 years in coming to grips with DAT has been nothing less than astonishing. These investigations are truly science of the highest order effectively directed at a human problem of enormous and increasing scope.

**Treatments and Outcomes in DAT** There is as yet no known treatment for DAT—medical, psychosocial, retraining-based, or rehabilitative, including attempts at preserving or replenishing brain ACh—that produces a sustained reversal or interruption of the deteriorating course. Until some means of accomplishing such an effect appears, we will have to content ourselves with palliative measures that diminish patient and caregiver distress and relieve as far as possible those complications of the disorder, such as combativeness, that increase the difficulties of management.

Concerning the latter objectives, Fisher and Carstensen (1990) reviewed the literature on behavioral approaches used to control several of the common problematic behaviors that are associated with DAT (and with other dementing disorders as well), such as wandering off, incontinence, inappropriate sexual behavior, and inadequate self-care skills. Because behavioral approaches need not be dependent on complex cognitive and communicational abilities, which are apt to be lacking in these patients, they may be particularly appropriate for therapeutic intervention with this group. In general, reports of results are moderately encouraging in terms of reducing unnecessary frustration and embarrassment for the patient and difficulty for the caregiver.

There has also been active treatment research focused on the consistent findings of ACh depletion in DAT. The reasoning here is that it might be possible to improve functioning by administering drugs that enhance the availability of brain ACh. Currently, the most effective way of doing so is by inhibiting the production of the principal enzyme involved in the metabolic breakdown of ACh, acetylcholinesterase. This is the rationale for the newly available drug tacrine (Cognex). Roth (1993) describes this type of pharmacologic intervention as "promising," and we would hope this prediction to be confirmed in future research. The limited findings so far available, however, suggest effects that are mostly quite limited and inconsistent (Whitehouse, 1993). Several other types of potentially cognition-enhancing drugs are currently being studied (Cardenas, 1993).

Other medications may be of some help for patients who experience difficulty in modulating their emotions and impulses. Some depressed DAT patients respond reasonably well to antidepressant or stimulant medication. Where medications are used, however, dosages must be carefully monitored because unanticipated effects are common and because the frequently debilitated state of these patients makes them susceptible to an exaggerated response.

As we have seen, neuronal cells that have died with the advance of Alzheimer's neuropathology are permanently lost; hence, even if some treatment were found to terminate a patient's disease, he or she would still be left seriously impaired. The real key to effective intervention must therefore be seen as preventive, or at least as deployable at the first sign of Alzheimer's onset, sparing the bulk of the brain's neurons. Eventually, for example, we might be able to identify and reduce or eliminate the environmental hazards that play a role in stimulating the development of Alzheimer's (Gatz et al., 1994). Clearly, however, the most promising development in regard to prevention possibilities relates to the apolipoprotein (ApoE) research described above. Conceivably, it will prove possible to fashion interventions—for example by administering targeted drugs—that counteract pathogenic processes associated with inheritance of the high-risk ApoE genes. That would truly be a momentous achievement.

In the meantime, any comprehensive approach to therapeutic intervention must consider the extremely difficult situation of caregivers. With advancing DAT, they are confronted not only with many difficult management problems but also with the "social death" of the patient as a person and their own "anticipatory grief" (Gilhooly et al., 1994). They are, as a group, at extraordinarily high risk for depression (Cohen & Eisdorfer, 1988). They tend to consume high quantities of psychotropic medication themselves and to report many stress symptoms (George, 1984; Hinrichsen & Niederehe, 1994). Because the basic problem usually seems to be one of high and sustained stress, any measures found successful in the reduction and management of stress and the enhancement of coping resources could be helpful in easing caregivers' burdens (Costa, Whitfield, & Stewart, 1989). Group support programs, for example, may produce measurable reductions in experienced stress and depression (e.g., Glosser & Wexler, 1985; Hebert et al., 1994; Kahan et al., 1985).

Whether or not, or at what point, to institutionalize a DAT patient whose requirements for care threaten to overwhelm his or her spouse or other family members can be a vexing and emotional decision (Cohen et al., 1993). It can also be one with significant financial implications because, on average, nursing home care is about twice as costly as home care (Hu, Huang, & Cartwright, 1986). As we have seen, most DAT patients are cared for at home, mostly for emotional reasons, such as continuing love, loyalty, and a sense of obligation to the stricken parent or partner. In one sense at least, the home care decision is a justifiable one; the move to an institution, particularly one lacking in social stimulation and support, may result in an abrupt worsening of symptoms and sometimes a markedly enhanced rate of deterioration—demonstrating once again the power of psychosocial influences even in the case of widespread brain destruction. On the other hand, the emergence of marked confusion, gross and argumentative demeanor, stuporous depression, inappropriate sexual behavior, and disorientation for time, place, and person, not to mention possible sudden eruption of combative violence, can put an intolerable strain on caregivers. Because in all likelihood such conditions will worsen over time, wisdom dictates an early rather than a late removal to an institution, which in any event is where most DAT patients will have to spend their final weeks or months.

**A Note on Vascular Dementia** Vascular (formerly multi-infarct) dementia (VAD), frequently confused with DAT because of its somewhat similar clinical picture and its increasing incidence and prevalence rates with advancing age, is actually an entirely different disease in terms of its underlying neuropathology. In this disorder, a series of cerebral infarcts—interruptions of the blood supply to parts of the brain because of arterial disease, commonly known as strokes—cumulatively destroy neurons over expanding brain regions. The affected regions become soft and may degenerate over time, leaving only cavities. Although this disorder tends to have a more heterogeneous early clinical picture (Wallin & Blennow, 1993), the progressive loss of cells leads to brain atrophy and behavioral impairments that ultimately mimic those of DAT. The decline, however, is less smooth in course because of (a) the discrete character of infarct events and the processes they initiate; (b) variations over time in the volume of blood delivered by a seriously clogged artery, producing variations in the functional adequacy of cells that have not yet succumbed to oxygen deprivation; and (c) a tendency to be associated with more severe behavioral complications (Sultzer et al., 1993). VAD is far less common than DAT, accounting for only some 10 percent of dementia cases. One reason for this is that VAD has a much shorter average course because of a patient's vulnerability to sudden death from a large infarct or one that affects vital centers. Occasionally, an unfortunate patient will be discovered to have both DAT and VAD.

The medical treatment of VAD, while hazardous and complicated, offers slightly more hope at this time than that of DAT. Unlike DAT, the basic problem of cerebral arteriosclerosis can be medically managed to some extent, perhaps decreasing the likelihood of further strokes.

The psychological and behavioral aspects of the dementia caused by DAT and VAD are similar in many respects, and any management measure found useful in one is likely to be applicable in the other. Likewise, the maintenance of any gains achieved cannot be taken for granted because of the generally progressive nature of the underlying brain pathology. The daunting problems facing caregivers are also much the same in the two conditions, indicating the appropriateness of support groups, stress reduction techniques, and the like.

## Disorders Involving Head Injury

Since ancient times, traumatic brain injuries have provided a rich source of material for speculation about mental functions. Hippocrates pointed out that injuries to the head could cause sensory and motor disorders, and Galen included head injuries among the major causes of mental disorders. Head injuries occur frequently, particularly as a result of falls, blows, and accidents. It has been estimated that well over a million people in the United States suffer head injuries each year in automobile and industrial accidents; a sizable number of cases are the result of bullets or other objects actually penetrating the cranium. Significant brain damage is sustained in some 300,000 of these instances (Chance, 1986). Relatively few people with head injuries find their way into mental hospitals because many head injuries do not involve appreciable damage to the brain, and even where they do psychopathological complications are often not observed.

**The Clinical Picture in Disorders with Head Injuries** Clinicians distinguish three general types of traumatic head injury because the clinical pictures and residual problems vary somewhat among them: (a) closed head injury (CHI, in which the cranium remains intact); (b) penetrating head injury (PHI, in which the cranium, as well as the underlying brain, are penetrated by some object, such as a bullet) and (c) skull fracture, with or without compression of the brain by fragmented bone concavity. Posttrauma epilepsy, for example, is unusual in CHI but a rather common outcome of the other two forms of head injury. The damage to the brain in CHI is indirect, so to speak, produced by inertial forces that cause it to come into violent contact with the interior skull wall, or rotational forces that twist the brain mass relative to the brain stem.

Neuropsychologically significant head injuries usually give rise to immediate acute reactions, such as unconsciousness and disruption of circulatory, metabolic, and neurotransmitter regulation. Normally, if a head injury is sufficiently severe to result in unconsciousness, the person experiences *retrograde amnesia,* or inability to recall events immediately preceding the injury. Apparently, such trauma interferes with the brain's capacity to consolidate into long-term storage the events that were still being processed at the time of the trauma. *Anterograde amnesia,* which refers to an inability to effectively store in memory events happening during variable periods of time *after* the trauma, is also occasionally observed and is regarded by many as a negative prognostic sign.

A person rendered unconscious by a head injury usually passes through stages of stupor and confusion on the way to recovering clear consciousness. This recovery of consciousness may be complete in the course of minutes, or it may take hours or days. In rare cases an individual may live for extended periods of time without regaining consciousness, a condition known as coma. In such cases the prognosis for substantial improvement is poor. In some instances, significant cognitive or personality alterations following injury are observed even where a person experiences no loss of consciousness.

The persistence and severity of posttrauma disruptions of brain function depend on the degree and type of injury. They may lead to early death or may clear up entirely. Quite often they develop into chronic disorders in which the individual's future cognitive and behavioral functioning is compromised. In relatively severe but nonfatal brain injury, most of the recovery that will be experienced tends to occur in the earliest posttrauma phase, although sometimes return of function may still occur after several years. Individual courses of recovery are highly variable (Crepeau & Scherzer, 1993; Powell & Wilson, 1994). In DSM-IV, brain injuries having notable, long-standing effects on adaptive functioning are coded on Axis I using the appropriate syndromal descriptive phrase, with the qualifier "due to head trauma."

Following a severe cerebral injury, a person's pulse, temperature, blood pressure, and important aspects of brain metabolism are all affected, and survival may be uncertain. The duration of the coma is generally related to the severity of the injury. If the patient survives, coma may be followed by delirium, in which acute excitement is manifested, with disorientation, hallucinations, and generally agitated, restless, and confused activity. Often the patient talks incessantly in a disconnected fashion, with no insight into the disturbed condition. Gradually the confusion clears up and the individual regains contact with reality. Again, the severity and duration of residual symptoms depend primarily on the nature and extent of the cerebral damage, the premorbid personality of the patient, and the life situation to which he or she will return.

Fortunately, the brain is an extraordinarily well protected organ; but even so, a hard blow on the head may result in a skull fracture in which portions of bone press on or are driven into the brain tissue. Even without a fracture, the force of the blow may result in small, pinpoint hemorrhages throughout the brain or in the rupturing of larger blood vessels in the brain. Some degree of bleeding, or *intracranial hemorrhage,* can occur with even relatively low-impact head injuries. In severe injuries, there may be gross bleeding or hemorrhaging at the site of the damage. Enough blood may accumulate within the rigid confines of the skull that disruptive pressure is exerted on neighboring regions of the brain; a common form of this problem is the ***subdural hematoma,*** which, if not relieved by aspiration of the excess blood, may endanger vital brain functions or produce permanent neuronal damage. When the hemorrhaging involves small spots of bleeding—often microscopic sleeves of red cells encircling tiny blood vessels—the condition is referred to as ***petechial hemorrhages.*** Some evidence shows tiny, scattered petechial hemorrhages in most brain injuries, but in fatal cases they are usually multiple or generalized throughout the brain. Serious levels of brain swelling, or ***cerebral edema,*** occur in many cases of severe damage, increasing the risk of significant mental impairment or death unless promptly treated.

*This police officer, who received a gunshot head wound in the line of duty, is receiving therapy to improve muscle tone and function in his left arm.*

Professional boxers are likely to suffer such petechial hemorrhaging from repeated blows to the head; they may develop a form of encephalopathy (characterized by an area or areas of permanently damaged brain tissue) from the accumulated damage of such injuries. Consequently, some former boxers suffer from impaired memory, slurred speech, inability to concentrate, involuntary movements, and other symptoms—a condition popularly referred to as being "punch-drunk." Johnson (1969) found abnormal electroencephalograms in 10 of 17 retired boxers; Earl (1966) noted that two former welterweight champions suffered so much brain damage in their professional fights that they were confined in mental institutions before they reached the age of 30.

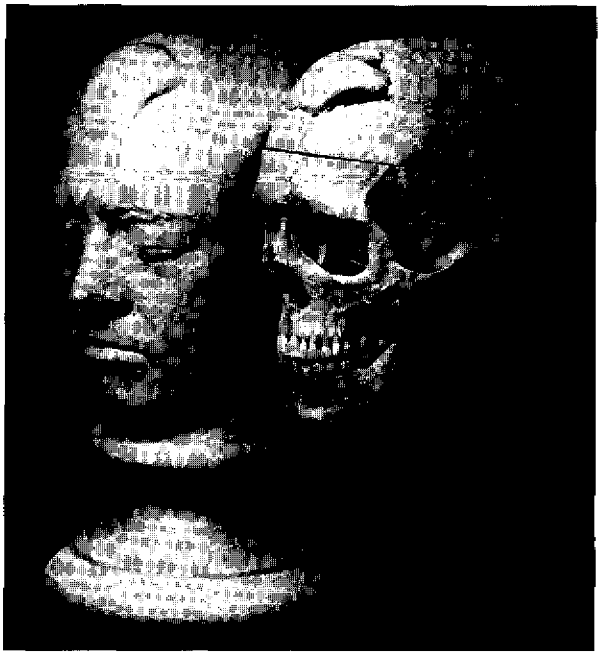
Even where an injury seems relatively mild with good return of function, careful neuropsychological assessment may reveal subtle residual impairment. Large numbers of relatively mild closed-head brain *concussions* (violent shock to tissues) and *contusions* (bruises) occur every year as a result of auto collisions, athletic injuries, falls, and other mishaps. Temporary loss of consciousness and postimpact confusion are the most common and salient immediate symptoms. There is considerable controversy about whether these mild brain injuries produce significant long-standing symptoms or impairments of various abilities (Dikmen & Levin, 1993; Zasler, 1993). Brown, Fann, and Grant (1994), for example, have made a strong argument that "postconcussional disorder" should be included in the DSM as a separate diagnosis based on evidence of diffuse postinjury changes in cognitive ability, personality, brain anatomy and electrophysiology (EEG), and general life functioning. So far, at least, that argument has not prevailed, although the recommended diagnosis is included as one of a large number of provisional candidates said to need "further study" in a DSM-IV Appendix.

Perhaps the most famous historical example of traumatic brain injury is the celebrated American crowbar case reported by Dr. J. M. Harlow in 1868 (Dr. Harlow's original report was recently reprinted in *History of Psychiatry,* 1993, Vol. 4, pp. 271–81). Because it is of both historical and descriptive significance, it merits our attention:

> The accident occurred in Cavendish, Vt., on the line of the Rutland and Burlington Railroad, at that time being built, on the 13th of September, 1848, and was occasioned by the premature explosion of a blast, when this iron, known to blasters as a tamping iron, and which I now show you, was shot through the face and head.
>
> The subject of it was Phineas P. Gage, a perfectly healthy, strong and active young man, twenty-five years of age . . . Gage was foreman of a gang of men employed in excavating rock, for the road way. . . .
>
> The missile entered by its pointed end, the left side of the face, immediately anterior to the angle of the lower jaw, and passing obliquely upwards, and obliquely backwards, emerged in the median line, at the back part of the frontal bone, near the coronal suture. . . .
>
> The iron which thus traversed the head, is round and rendered comparatively smooth by use, and is three feet seven inches in length, one and one fourth inches in its largest diameter, and weighs thirteen and one fourth pounds. . . .
>
> The patient was thrown upon his back by the explosion, and gave a few convulsive motions of the extremities, but spoke in a few minutes. His men (with whom he was a great favorite) took him in their arms and carried him to the road, only a few rods distant, and put him into an ox cart, in which he rode, supported in a sitting posture, fully three quarters of a mile to his hotel. He got out of the cart himself, with a little assistance from his men, and an hour afterwards (with what I could aid him by taking hold of his left arm) walked up a long flight of stairs, and got upon the bed in the room where he was dressed. He seemed perfectly conscious, but was becoming exhausted from the hemorrhage, which by this time, was quite profuse, the blood pouring from the lacerated sinus in the top of his head, and also finding its way into the stomach, which ejected it as often as every fifteen or twenty minutes. He bore his sufferings with firmness, and directed my attention to the hole in his cheek, saying, "the iron entered there and passed through my head."

Some time later Dr. Harlow made the following report:

> His physical health is good, and I am inclined to say that he has recovered. Has no pain in head, but says it has a queer feeling which he is not able to describe. Applied for his situation as foreman, but is undecided whether to work or travel. His contractors, who regarded him as the



*A cast of the head and the actual skull of Phineas Gage. Note the places in the skull pierced by the iron rod.*

> most efficient and capable foreman in their employ previous to his injury considered the change in his mind so marked that they could not give him his place again. The equilibrium or balance, so to speak, between his intellectual faculties and animal propensities, seems to have been destroyed. He is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operations, which are no sooner arranged than they are abandoned in turn for others . . . his mind is radically changed, so decidedly that his friends and acquaintances said he was "no longer Gage."

It is evident from the above account that Gage acquired a severe frontal brain wound as well as a neuropsychological personality syndrome from his encounter with the crowbar. As Stuss and colleagues (1992) have noted, Gage's persistent posttrauma difficulties are fairly characteristic for severe frontal-lobe damage; emotional dyscontrol and personality alterations, including impairment of self-reflective awareness, are often prominent features of behavior change due to this type of injury. In general, however, personality disturbances secondary to traumatic brain injury are somewhat unpredictable owing to the varied structural pathology apt to be involved in such injuries (Prigatano, 1992).

**Treatments and Outcomes** Immediate treatment for brain damage due to head injury is primarily a medical matter. Prompt treatment may prevent further injury or damage—for example, when pooled blood under pressure must be removed from the skull. In moderate to severe cases, immediate medical treatment may have to be supplemented by a long-range program of reeducation and rehabilitation.

Although many head trauma patients show few residual effects from their injury, particularly if they have experienced only a brief loss of consciousness, other patients sustain definite and long-lasting impairment. Common aftereffects of moderate brain injury are chronic headaches, anxiety, irritability, dizziness, easy fatigability, and impaired memory and concentration. Where the brain damage is extensive, a patient's general intellectual level may be markedly reduced, especially if he or she has suffered severe temporal- or parietal-lobe lesions. Most victims have significant delays in returning to their occupations, and many are unable to return at all (Dikmen et al, 1994); other losses of adult social roles are also common (Hallett et al., 1994). In addition, various specific neurological and psychological defects may follow localized brain damage, as we have seen. Some 2–4 percent of head injury cases develop posttraumatic epilepsy, usually within two years of the head injury but sometimes much later.

In a minority of brain injury cases, notable personality changes occur, such as those described in the historic case of Phineas Gage. Other kinds of personality changes include passivity, loss of drive and spontaneity, agitation, anxiety, depression, and paranoid suspiciousness. Like cognitive changes, the kinds of personality changes that emerge in severely damaged people will depend, in large measure, on the site and extent of their injury (Prigatano, 1992).

The great majority of people suffering from mild concussions improve to a near normal status within a short time. With moderate brain injuries, it takes longer for patients to reach their maximum level of improvement, and many suffer from headaches and other symptoms for prolonged periods. A few develop chronic, incapacitating symptoms. In severe brain injury cases, the prognosis is less favorable

(Jennett et al., 1976; Powell & Wilson, 1994). Many of these patients have to adjust to lower levels of occupational and social functioning (Dikmen et al., 1994), while others are so impaired intellectually that they require continuing supervision and, sometimes, institutionalization. Even in cases where considerable amounts of brain tissue have been destroyed, however, some patients are able to become socially independent. In many cases there is improvement with time, due largely to reeducation and to intact brain areas taking over new functions (Powell & Wilson, 1994).

In general, the following factors indicate a favorable prognosis in cases of head injury: (a) a short period of unconsciousness or posttraumatic amnesia; (b) minimal or no cognitive impairment; (c) a well-integrated pre-injury personality; (d) higher educational attainment; (e) stable pre-injury work history; (f) motivation to recover or make the most of residual capacities; (g) a favorable life situation to which to return; (h) early intervention; and (i) an appropriate program of rehabilitation and retraining (Brooks, 1974; Dikmen et al., 1994; Diller & Gordon, 1981; Mackay, 1994).

The last-mentioned factor, crucial for the future functioning of many brain-injured individuals (Giles, 1994), and demonstrably effective when approached in a comprehensive way (e.g., Malec et al., 1993), is unfortunately far from generally available (Chance, 1986). Even where such specialized treatment centers are conveniently located, they may be too expensive for patients to take advantage of them. Encouraging in recent years is a trend toward community-wide organization to cope with the rehabilitation challenges of brain-injured persons (e.g., Huber & Edelberg, 1993; McLaughlin & Peters, 1993; Seaman et al., 1993).

Other factors may also have a direct bearing on the outcome of brain injuries. As we mentioned earlier, the results of brain damage in young childhood differ from those in adolescence and adulthood, although in both instances the results may range from death to any number of neurological disorders, including epilepsy and mental retardation. Moreover, the outlook for individuals who are also victims of alcoholism, drug dependence, or other organic conditions may be unfavorable. Alcoholics, in particular, are prone to head injuries and other accidents and do not have good improvement records, possibly because many of them also have brain deficits related to excessive drinking (Mearns & Lees-Haley, 1993). Severe emotional conflicts sometimes appear to predispose an individual to accidents and also may delay recovery. Although malingering is thought to be rare in brain injury cases, the hope of receiving monetary compensation—for example, from an insurance settlement—may influence individuals to exaggerate and maintain symptoms.

## MENTAL RETARDATION

The American Psychiatric Association (1994) in DSM-IV defines **mental retardation** as "significantly subaverage general intellectual functioning . . . that is accompanied by significant limitations in adaptive functioning" (p. 39) in certain skill areas such as self-care, work, health, and safety. To qualify for the diagnosis, these problems must have begun before the age of 18. Mental retardation is thus defined in terms of level of behavioral performance. The definition says nothing about causal factors—which may be primarily biological, psychosocial, sociocultural, or a combination of these. By definition, any functional equivalent of mental retardation that has its onset after age 17 must be considered a dementia rather than mental retardation. The distinction is an important one, because, as was pointed out early in the chapter, the psychological situation of a person who acquires a pronounced impairment of intellectual functioning after attaining maturity is vastly different from that of a person whose intellectual resources were subnormal throughout all or most of his or her development.

In contrast to other developmental disorders, mental retardation is coded (with reference to a particular level as described below) on Axis II of DSM-IV, along with the personality disorders. The reason for this inconsistency is not explained in the DSM manual. In any event, mental retardation, like other DSM diagnostic categories, is treated as a specific type of disorder, although it may occur in combination with other disorders appearing on either Axis I or Axis II. In fact other psychiatric disorders, especially psychoses (Jacobson, 1990), occur at a markedly higher rate among retarded people than in the general population (Borthwick-Duffy, 1994; Sturmey & Sevin, 1993).

Mental retardation occurs among children throughout the world. In its most severe forms, it is a source of great hardship to parents as well as an economic and social burden on a community. The point prevalence rate of diagnosed mental retardation in the United States is estimated to be about 1 percent, which would indicate a population estimate of some 2.6 million people. This figure is considerably lower than the hypothetical estimate based on an IQ cutoff score of about 70, which is the dividing point used by DSM-IV. Thus many—probably a majority—of persons with IQs below 70 are not officially diagnosed as retarded, suggesting that they are "making it" in terms of meeting adaptational demands at a minimally acceptable level. Nevertheless, most states have laws providing that persons with IQs below 70 who show socially incompetent or persistently problematic behavior can be classified as mentally retarded, and if judged otherwise unmanageable may be placed in an institution. Informally, IQ scores between about 70 and 90 are often referred to as "borderline" or (in the upper part of the range) "dull-normal."

Initial diagnoses of mental retardation seem to increase markedly at ages 5 to 6, to peak at age 15, and to drop off sharply after that. For the most part, these age-related changes in time of first diagnosis reflect changes in life demands. During early childhood, individuals with only a mild degree of intellectual impairment, who constitute the vast majority of the mentally retarded, often appear to be normal. Their subaverage intellectual functioning becomes apparent only when difficulties with schoolwork lead to a diagnostic evaluation. When adequate facilities are available for their education, children in this group can usually master essential school skills and achieve a satisfactory level of socially adaptive behavior. Following the school years, they usually make a more or less acceptable adjustment in the community and thus lose the identity of being mentally retarded.

## Levels of Mental Retardation

It is important to remind ourselves once again that any classification system in the behavioral field will have strong features of both arbitrariness and pragmatism. In mental retardation, attempts to define varying levels of impairment have tended to rely increasingly on measurement—largely by means of standardized intelligence (IQ) tests (Robinson & Robinson, 1976). In the previously quoted DSM-IV definition, for example, the phrase "significantly subaverage general intellectual functioning" translates directly and officially into an IQ test score that is more than two standard deviations below the population mean. That mean, which represents the average test performance for children of a given age, is 100. The standard deviation of most IQ tests is about 15 points, and approximately two-thirds of the population score between plus and minus one standard deviation unit from the mean—that is, between 85 and 115. Thus a score of two standard deviations below the mean would be an IQ of approximately 70. Under the assumption that IQ scores are normally distributed in the familiar bell-shaped form, about 2.5 percent of the population would score in the range below IQ 70.

It is not necessarily improper to define mental retardation in this way, provided we keep in mind the implications of the definition. The original IQ tests were devised for the explicit purpose of predicting academic achievement among schoolchildren. Other IQ tests developed later were also validated largely on school performance and on the basis of how well they could predict scores on the original tests. Generally, then, what IQ tests measure is an individual's likely level of success in dealing with conventional academic materials, and in fact they do this very well when properly utilized. Thus when we speak of varying levels of mental retardation, we are to a great extent speaking of levels of ability to succeed at schoolwork.

Of course, this reliance on IQ scores is tempered somewhat by the other main part of the definition—the presence of concurrent "significant limitations in adaptive functioning." The same dual criteria are involved in the officially recognized "levels" of retardation, although the IQ score often tends in practice to be the dominant consideration. This emphasis on the IQ score is reasonable at the lower end of the scale, because a person with an IQ of 50 or below will inevitably exhibit gross deficiencies in overall adaptive behavior as well. At the higher ranges of "retarded" IQ scores, however, behavioral adaptiveness and IQ score seem to be at least partially independent of one another. It should also be noted that differing social environments, such as rural versus urban, are differentially challenging both intellectually and behaviorally.

The DSM-IV recognizes four degrees of severity of mental retardation. These are indicated in the table below, together with their corresponding IQ ranges:

| Diagnosed Level of Mental Retardation | Corresponding IQ Range |
|---|---|
| Mild retardation | 50–55 to approximately 70 |
| Moderate retardation | 35–40 to 50–55 |
| Severe retardation | 20–25 to 35–40 |
| Profound retardation | below 20–25 |

In former times the American Psychiatric Association (publisher of DSM-IV) and the American Association on Mental Retardation (AAMR) generally agreed on definitions of mental retardation and specifications of levels or degrees of it. In 1992 the AAMR broke away from this tradition (Luckasson et al., 1992), adopting IQ 75 as the cutoff point for the diagnosis of mental retardation (thus expanding the pool of eligibles). In addition, the AAMR proposal substitutes "patterns and intensity of supports needed" (intermittent, limited, extensive, and pervasive) for the levels of severity indicated above; the "steps" of the two systems for characterizing severity are not directly comparable. Several more technical revisions of standard diagnostic procedure are also called for in the AAMR approach. Many professionals have voiced criticism of the new AAMR-proposed guidelines and view this divergence of approaches as unfortunate and as increasing the potential for disagreement and confusion in rendering the mental retardation diagnosis (see MacMillan, Gresham, & Siperstein, 1993). It seems clear, however, that the AAMR intent was to advance its agenda to provide increased services for retarded persons.

The various levels of mental retardation, as defined in DSM-IV, are described in greater detail in the following sections:

1. *Mild mental retardation.* Mildly retarded individuals constitute by far the largest number of those diagnosed as mentally retarded. Within the educational context people in this group are considered "educable," and their intellectual levels as adults are comparable with those of average 8- to 11-year-old children. Statements such as the latter, however, should not be taken too literally. A mildly retarded adult with a "mental age" of, say, 10 (that is, intelligence test performance is at the level of the average 10-year-old) may not in fact be comparable to the normal 10-year-old in information-processing ability (Weiss, Weisz, & Bromfield, 1986).

The social adjustment of mildly retarded people often approximates that of adolescents, although they tend to lack normal adolescents' imagination, inventiveness, and judgment. Ordinarily, they do not show signs of brain pathology or other physical anomalies, but often they require some measure of supervision because of their limited abilities to foresee the consequences of their actions. Individuals at a somewhat higher, "borderline" IQ level (about 71–84) may also need special services to maximize their potentials (Zetlin & Murtaugh, 1990). With early diagnosis, parental assistance, and special educational programs, the great majority of borderline and mildly retarded individuals can adjust socially, master simple academic and occupational skills, and become self-supporting citizens (Schalock, Harper, & Carver, 1981).

2. *Moderate mental retardation.* Moderately retarded individuals are likely to fall in the educational category of "trainable," which means that they are presumed able to master certain routine skills, such as cooking or minor janitorial work, if provided specialized instruction in these activities. In adult life, individuals classified as moderately retarded attain intellectual levels similar to those of average four- to seven-year-old children. Although some can be taught to read and write a little and may manage to achieve a fair command of spoken language, their rate of learning is slow, and their level of conceptualizing extremely limited. Physically, they usually appear clumsy and ungainly, and they suffer from bodily deformities and poor motor coordination. Some of these moderately retarded people are hostile and aggressive; more typically they present an affable, unthreatening personality picture. Very rarely, extraordinary specialized skills, such as outstanding musical ability (see Hill, 1975), are found in moderately retarded individuals; well documented empirically, these phenomena have never been adequately explained. In general, with early diagnosis, parental help, and adequate opportunities for training, most moderately retarded individuals can achieve partial independence in daily self-care, acceptable behavior, and economic usefulness in a family or other sheltered environment.

*Mildly retarded individuals constitute the largest number of those labeled mentally retarded. With help, a great majority of these individuals can adjust socially, master simple academic and occupational skills, and become self-supporting citizens.*

3. *Severe mental retardation.* Severely retarded individuals are sometimes referred to as dependent retarded. In these individuals, motor and speech development are severely retarded, and sensory defects and motor handicaps are common. They can develop limited levels of personal hygiene and self-help

skills, which somewhat lessen their dependence, but they are always dependent on others for care. However, many profit to some extent from training and can perform simple occupational tasks under supervision.

4. *Profound mental retardation.* The term *life-support retarded* is sometimes used to refer to profoundly retarded individuals. Most of these people are severely deficient in adaptive behavior and unable to master any but the simplest tasks. Useful speech, if it develops at all, is rudimentary. Severe physical deformities, central nervous system pathology, and retarded growth are typical; convulsive seizures, mutism, deafness, and other physical anomalies are also common. These individuals must remain in custodial care all their lives. They tend, however, to have poor health and low resistance to disease and thus a short life expectancy.

Severe and profound cases of mental retardation can usually be readily diagnosed in infancy because of the presence of obvious physical malformations, grossly delayed habit training (e.g., taking solid food), and other obvious symptoms of abnormality. Although these individuals show a marked impairment of overall intellectual functioning, they may have considerably more ability in some areas than in others.

Contrary to common understanding, the distribution of IQ scores does not precisely fit "normal curve" expectations, especially in the lower IQ or mental retardation range. This range shows a substantial frequency bulge, disrupting the normal taper of the bell curve in its descent toward a theoretical zero occurrence of cases at its leftmost (lowest IQ) extreme. This finding suggests the operation of an intruding factor that tends to inflate beyond normal-curve expectancy the numbers of cases at lower IQ ranges—specifically the presence of major congenital abnormalities, brain injuries, or both that are not characteristic of normally distributed phenomena. The bulge is frequently called the "bump of pathology." The next section addresses these pathological anomalies.

## Brain Defects in Mental Retardation

Some cases of mental retardation—something on the order of 25 percent—occur in association with known organic brain pathology. In these cases, retardation is virtually always at least moderate, and it is often severe. Profound retardation, fortunately rare, always includes obvious organic impairment. Organically caused retardation is in essential respects similar to dementia as earlier described, except for a different history of prior functioning. In fact, in the past, a young person with organically caused retardation was referred to as *amented,* as distinct from a demented person. In this section we will consider five biological conditions that may lead to mental retardation, noting some of the possible interrelations between them. Then we will review some of the major clinical types of mental retardation associated with these organic causes.

**Genetic-Chromosomal Factors** Mental retardation tends to run in families. This tendency is particularly true of mild retardation. Poverty and sociocultural deprivation, however, also tend to run in families, and with early and continued exposure to such conditions, even the inheritance of average intellectual potential may not prevent subaverage intellectual functioning.

Genetic and chromosomal factors play a much clearer role in the etiology of relatively infrequent but more severe types of mental retardation, such as Down syndrome (discussed below) or an inheritable condition known as *fragile X,* a constriction or breaking off of the end portion of the long arm of the X sex chromosome that appears determined by a specific gene defect (de Vries et al., 1994). In such conditions genetic aberrations are responsible for metabolic alterations that adversely affect the brain's development. Genetic defects leading to metabolic alterations may, of course, involve many other developmental anomalies besides mental retardation. In general, mental retardation associated with known genetic-chromosomal defects is moderate to severe in degree.

**Infections and Toxic Agents** Mental retardation may be associated with a wide range of conditions due to infection. If a pregnant woman is infected with syphilis or HIV-1, or if she gets German measles, her child may suffer brain damage. Brain damage may also result from infections occurring after birth, such as viral encephalitis.

A number of toxic agents, such as carbon monoxide and lead, may cause brain damage during fetal development or after birth. In some instances, immunological agents, such as antitetanus serum or typhoid vaccine, may lead to brain damage. Similarly, certain drugs, including an excess of alcohol, taken by a pregnant woman may lead to congenital malformations; an overdose of drugs administered to an infant may result in toxicity and brain damage. In rare cases, brain damage results from incompatibility in blood types between mother and fetus—conditions known as Rh, or ABO, system incompatibility.

Fortunately, early diagnosis and blood transfusions can now minimize the effects of such incompatibility.

**Prematurity and Trauma (Physical Injury)** Follow-up studies of children born prematurely and weighing less than about 5.5 pounds at birth have revealed a high incidence of neurological disorders and often mental retardation. In fact, small premature babies are many times more likely to be mentally retarded than normal-sized infants.

Physical injury at birth can also result in retardation. Isaacson (1970) has estimated that in 1 birth out of 1000 brain damage occurs that will prevent the child from reaching the intelligence level of an average 12-year-old. Although the fetus is normally well protected by its fluid-filled bag during gestation, and its skull appears designed to resist delivery stressors, accidents do happen during delivery and after birth. Difficulties in labor due to malposition of the fetus or other complications may irreparably damage the infant's brain. Bleeding within the brain is probably the most common result of such birth trauma. *Hypoxia*—lack of sufficient oxygen to the brain stemming from delayed breathing or other causes—is another type of birth trauma that may damage the brain.

**Ionizing Radiation** In recent decades a good deal of scientific attention has been focused on the damaging effects of ionizing radiation on sex cells and other bodily cells and tissues. Radiation may act directly on the fertilized ovum or may produce gene mutations in the sex cells of either or both parents, which, in turn, may lead to defective offspring. Sources of harmful radiation were once limited primarily to high-energy X rays used in medicine for diagnosis and therapy, but the list has grown to include nuclear weapons testing and leakages at nuclear power plants, among others.

**Malnutrition and Other Biological Factors** It has long been believed that dietary deficiencies in protein and other essential nutrients during early development can result in irreversible physical and mental damage. However, current thinking on the association between malnutrition and mental retardation outcomes suggests that the direct causal link originally posited may be oversimplified. In a recent review of the problem, Ricciuti (1993) cites growing evidence that the negative impact of malnutrition on mental development may be more indirect by altering a child's responsiveness, curiosity, and motivation to learn. These losses would then lead, according to this hypothesis, to a relative retardation of intellectual facility. If Ricciuti is right, at least some malnutrition-induced intellectual deficit may be viewed as a special case of psychosocial deprivation, also believed to be implicated in retardation outcomes, as described below.

A limited number of cases of mental retardation are clearly associated with organic brain pathology. In some instances—particularly of the severe and profound types—the specific causes are uncertain or unknown, although extensive brain pathology is evident. In the following sections we will deal with three relatively well-understood types of organically caused mental retardation.

## Organic Retardation Syndromes

Mental retardation stemming primarily from biological causes can be classified into several recognizable clinical types, of which Down syndrome, phenylketonuria, and cranial anomalies will be discussed here. HIGHLIGHT 13.4 presents information on several other well-known forms.

**Down Syndrome** First described by Langdon Down in 1866, **Down syndrome** is the best known of the clinical conditions associated with moderate and severe mental retardation. About 1 in every 600 babies born in the United States is diagnosed as having Down syndrome, a condition that "has life-long implications for physical appearance, intellectual achievement and general functioning" (Golden & Davis, 1974, p. 7). The availability of ***amniocentesis*** and increasingly of ***chorionic villus sampling*** has made it possible to detect in utero the extra chromosome (47 rather than the normal 46) that is the hallmark of Down pathology. The possibility of elective abortion should the fetus prove chromosomally defective, while helpful for individual families, appears not to have affected substantially the overall incidence of the disorder. Because of demographic shifts, most Down syndrome infants in recent decades have been born to mothers under 35 years of age, not a group for whom chromosomal assessment is routinely recommended (Evans & Hamerton, 1985).

A number of physical features are often found among children with Down syndrome, but few of these children have all of the characteristics commonly thought of as typifying this group. In such children, the eyes appear almond-shaped, and the skin of the eyelids tends to be abnormally thick. The face and nose are often flat and broad, as is the back of the head. The tongue, which seems too large for the mouth, may show deep fissures. The iris of the

13.4

## Other Disorders Sometimes Associated with Mental Retardation

| Clinical Type | Symptoms | Causes |
|---|---|---|
| *No. 18 trisomy syndrome* | Peculiar pattern of multiple congenital anomalies, the most common being low-set malformed ears, flexion of fingers, small jaw, and heart defects | Autosomal anomaly of chromosome 18 |
| *Tay-Sachs disease* | Hypertonicity, listlessness, blindness, progressive spastic paralysis, and convulsions (death by the third year) | Disorder of lipoid metabolism, carried by a single recessive gene |
| *Turner's syndrome* | In females only; webbing of neck, increased carrying angle of forearm, and sexual infantilism | Sex chromosome anomaly (XO); mental retardation may occur but is infrequent |
| *Klinefelter's syndrome* | In males only; features vary from case to case, the only constant finding being the presence of small testes after puberty | Sex chromosome anomaly (XXY) |
| *Niemann-Pick's disease* | Onset usually in infancy, with loss of weight, dehydration, and progressive paralysis | Disorder of lipoid metabolism |
| *Bilirubin encephalopathy* | Abnormal levels of bilirubin (a toxic substance released by red cell destruction) in the blood; motor incoordination frequent | Often, Rh (ABO) blood group incompatibility between mother and fetus |
| *Rubella, congenital* | Visual difficulties most common, with cataracts and retinal problems often occurring together and with deafness and anomalies in the valves and septa of the heart | The mother's contraction of rubella (German measles) during the first few months of her pregnancy |

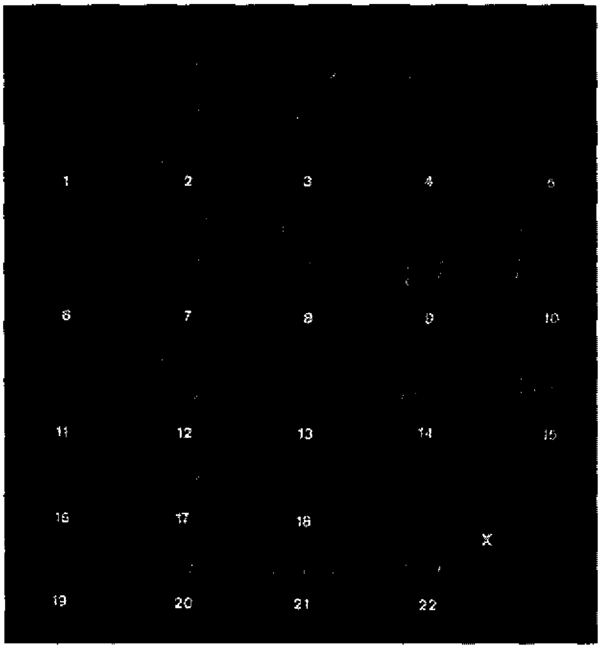
Based on American Psychiatric Association (1968, 1972); Clarke, Clarke, and Berg (1985); Holvey and Talbott (1972); Robinson and Robinson (1976).

eye is frequently speckled. The neck is often short and broad, as are the hands. The fingers are stubby, and the little finger is often more noticeably curved than the other fingers. Although facial surgery is sometimes tried to correct the more stigmatizing features, its success is often limited (Dodd & Leahy, 1989; Katz & Kravetz, 1989).

Interestingly, there appears to be little, if any, correlation between the extent of physical anomalies and the degree of mental retardation in individuals with Down syndrome. Death rates for children with Down syndrome have decreased dramatically in the past half century. In 1919, the life expectancy at birth for such children was about nine years; most of the deaths were due to gross physical problems, and a large proportion occurred in the first year. Thanks to antibiotics, surgical correction of lethal anatomical defects, and better general medical care, many more of these children now live to adulthood (Smith & Berg, 1976).

Despite their problems, children with Down syndrome are usually able to learn self-help skills, acceptable social behavior, and routine manual skills that enable them to be of assistance in a family or institutional setting. The traditional view has been that Down syndrome youngsters are unusually placid and affectionate. Research has questioned the validity of this generalization. These children may

*Today many more Down syndrome children are living to adulthood than in the past and are able to learn self-help, social, and manual skills. It is not unusual for Down syndrome children to be mainstreamed to some extent with unimpaired children, such as this girl in a ballet class. Down syndrome children tend to remain relatively unimpaired in their appreciation of spatial relationships and visual-motor coordination; they show their greatest deficits in verbal and language-related skills.*



*This is a reproduction (karyotype) of the chromosomes of a female patient with Down syndrome. Note the triple (rather than the normal paired) representation at chromosome 21.*

indeed be very docile, but probably in no greater proportion than normal youngsters; they may also be equally (or more) difficult in various areas (Bridges & Cicchetti, 1982). In general, the adequacy of a child's social relationships is positively correlated with both IQ level and a supportive home environment (Sloper et al., 1990).

Research has also suggested that the intellectual defect in Down syndrome may not be consistent across various abilities. Down syndrome children tend to remain relatively unimpaired in their appreciation of spatial relationships and in visual-motor coordination, although some recent evidence disputes this conclusion (Uecker et al., 1993); research data are quite consistent in showing that they have their greatest deficits in verbal and language-related skills (Azari et al., 1994; Mahoney, Glover, & Finger, 1981; Silverstein et al., 1982). Since spatial functions are known to be partially localized in the right cerebral hemisphere, and language-related functions in the left cerebral hemisphere, some investigators speculate that the syndrome is especially crippling to the left hemisphere.

Traditionally, the cause of Down syndrome was assumed to be faulty heredity. A number of early studies demonstrated, however, that more than a single case of Down syndrome in a family was unlikely, occurring in less than 1 family in 100 of those already affected. As a consequence of this finding, investigators turned to the study of metabolic factors and concluded that Down syndrome was probably due to some sort of glandular imbalance. Then, in 1959, the French scientists Lejeune, Turpin, and Gauthier found 47 chromosomes, instead of the usual 46, in several Down syndrome subjects. A trisomy of chromosome 21 (an error of reproductive cell division in which chromosome 21 is present in triplicate rather than the normal pair) has now been identified as a characteristic of Down syndrome children, being present in at least 94 percent of cases meeting strict Down syndrome criteria. As was noted earlier, it may be significant that this is the same chromosome that has been implicated in recent research on Alzheimer's disease, especially since persons with Down syndrome are at extremely high risk for Alzheimer's as they get into and beyond their late 30s (Bauer & Shea, 1986; Cole et al., 1994; Prasher & Kirshnan, 1993; Reid, 1985; Schapiro, Haxby, & Grady, 1992).

Researchers have long believed that the "extra" chromosome in Down syndrome is contributed by the mother. In 1973, however, it was learned that in some cases it is contributed by the father (Sasaki & Hara, 1973; Uchida, 1973). The reason for the trisomy of chromosome 21 is not clear, but the defect seems definitely related to parental age at conception. It has been known for many years that the incidence of Down syndrome increases on an accelerating slope (from the 20s on) with increasing age of the mother. A woman in her 20s has about 1 chance in 2000 of conceiving a Down syndrome baby, whereas the risk for a woman in her 40s is 1 in 50 (Holvey & Talbot, 1972). As in the case of all birth defects, the risk of having a Down syndrome baby is also high for very young mothers whose reproductive systems have not yet fully matured. The advanced maternal age correlation led naturally to the inference that an older woman's capacity to produce a chromosomally normal fetus was somehow impaired by the aging process. This observed effect obscured for many years a potential male contribution, since older men tend to have older women partners.

More recent research has strongly indicated that the father's age at conception is also implicated in Down syndrome, particularly at higher ages (Hook, 1980; Stene et al., 1981). In one study involving 1279 cases of Down syndrome in Japan, Matsunaga and associates (1978) demonstrated an overall increase in incidence with advancing paternal age when maternal age was controlled. The risk for fathers aged 55 years and over was more than twice that for fathers in their early 20s. Curiously, these investigators noted that, in their sample, fathers in their early 40s had a lower risk factor than slightly younger as well as older men.

Thus it seems that advancing age in either parent increases the risk of the trisomy 21 anomaly, although the maternal age effect is the larger one. As yet we do not understand how aging produces this effect. A reasonable guess is that aging is related to cumulative exposure to varied environmental hazards, such as radiation, that might have adverse effects on the processes involved in zygote formation or development.

**Phenylketonuria (PKU)** In **phenylketonuria (PKU)**, a baby appears normal at birth but lacks a liver enzyme needed to break down phenylalanine, an amino acid found in many foods. The genetic error results in retardation only when significant quantities of phenylalanine are ingested, something that is virtually certain to occur if the child's condition remains undiagnosed. If the condition is undetected, the amount of phenylalanine in the blood increases and eventually produces brain damage.

The disorder usually becomes apparent between 6 and 12 months after birth, although such symptoms as vomiting, a peculiar odor, infantile eczema, and seizures may occur during the early weeks of life. Often the first symptoms noticed are signs of mental retardation, which may be moderate to severe depending on the degree to which the disease has progressed. Lack of motor coordination and other neurological problems caused by the brain damage are also common, and often the eyes, skin, and hair of untreated PKU patients are very pale. PKU was unidentified until 1934, when a Norwegian mother sought to learn the reason for her child's mental retardation and peculiar musty odor. She consulted with many physicians to no avail until Dr. Asbjorn Folling found phenylpyruvic acid in the child's urine and concluded that the child had a disorder of phenylalanine metabolism (Centerwall & Centerwall, 1961).

Most older PKU patients show severe to profound mental retardation, with the median IQ of untreated phenylketonuric adults being about 20. Curiously, however, a number of seriously retarded PKU patients have PKU relatives with less severely affected intelligence. In addition, Perry (1970) reported the cases of two untreated PKU patients with superior intelligence. These findings have made PKU something of an enigma. It results from a liver enzyme deficiency involving one or more recessive genes, and 1 person in 70 is thought to be a carrier. There may be varying degrees of PKU, however, or another (unknown) genetic factor may lessen the destructive potential of the enzyme defect (Burns, 1972).

The early detection of PKU by examining urine for the presence of phenylpyruvic acid is now routine in developed countries, and dietary treatment (such as the elimination of phenylalanine-containing foods) and related procedures can be used to prevent the disorder. With early detection and treatment—preferably before an infant is six months old—the deterioration process can usually be arrested so that levels of intellectual functioning may range from borderline to normal. A few children suffer mental retardation despite restricted phenylalanine intake and other measures, however. Dietary restriction in late-diagnosed PKU may improve the clinical picture somewhat, but there is no real substitute for early detection and prompt intervention (Pavone et al., 1993).

For a baby to inherit PKU, it appears that both parents must carry the recessive genes. Thus when one child in a family is discovered to have PKU, it is especially critical that other children in the family be screened as well. Also, a pregnant PKU mother whose risk status has been successfully addressed by early dietary intervention may damage her at-risk fetus unless she maintains rigorous control of phenylalanine intake.

**Cranial Anomalies** Mental retardation is associated with a number of conditions that involve alterations in head size and shape and for which the causal factors have not been definitely established (Robinson

& Robinson, 1976). In the rare condition known as **macrocephaly** (large-headedness), for example, there is an increase in the size and weight of the brain, an enlargement of the skull, visual impairment, convulsions, and other neurological symptoms, resulting from the abnormal growth of glia cells that form the supporting structure for brain tissue. Other more common cranial anomalies include *microcephaly* and *hydrocephalus,* which we will discuss in more detail.

*Microcephaly.* The term **microcephaly** means "small-headedness." It refers to a type of mental retardation resulting from impaired development of the brain and a consequent failure of the cranium to attain normal size. In an early study of postmortem examinations of microcephalic individuals' brains, Greenfield and Wolfson (1935) reported that practically all cases examined showed development to have been arrested at the fourth or fifth month of fetal life.

The most obvious characteristic of microcephaly is the small head, the circumference of which rarely exceeds 17 inches, as compared with the normal size of approximately 22 inches. Penrose (1963) also described microcephalic youngsters as being invariably short in stature but having relatively normal musculature and sex organs. Beyond these characteristics, they differ considerably from one another in appearance, although there is a tendency for the skull to be cone-shaped, with a receding chin and forehead. Microcephalic children fall within the moderate, severe, and profound categories of mental retardation, but most show little language development and are extremely limited in mental capacity.

Microcephaly may result from a wide range of factors that impair brain development, including intrauterine infections and pelvic irradiation during the mother's early months of pregnancy (Koch, 1967). Miller (1970) noted a number of cases of microcephaly in Hiroshima and Nagasaki that apparently resulted from the atomic bomb explosions during World War II. The role of genetic factors is not clear, although there is speculation that a single recessive gene is involved in a primary, inherited form of the disorder (Robinson & Robinson, 1976). Treatment is ineffective once faulty development has occurred; at present, preventive measures focus on the avoidance of infection and radiation during pregnancy.

*Hydrocephalus.* **Hydrocephalus** is a relatively rare condition in which the accumulation of an abnormal amount of cerebrospinal fluid within the cranium causes damage to the brain tissues and enlargement of the skull. In congenital cases, the head is either already enlarged at birth or begins to enlarge soon thereafter, presumably as a result of a disturbance in the formation, absorption, or circulation of the cerebrospinal fluid (Robinson & Robinson, 1976). The disorder can also develop in infancy or early childhood, following the development of a brain tumor, subdural hematoma, meningitis, or other conditions. In these cases the condition appears to result from a blockage of the cerebrospinal pathways and an accumulation of fluid in certain brain areas.

The clinical picture in hydrocephalus depends on the extent of neural damage, which, in turn, depends on the age at onset and the duration and severity of the disorder. In chronic cases, the chief symptom is the gradual enlargement of the upper part of the head out of proportion to the face and the rest of the body. While the expansion of the skull helps minimize destructive pressure on the brain, serious brain damage occurs nonetheless. This damage leads to intellectual impairment and such other effects as convulsions and impairment or loss of sight and hearing. The degree of intellectual impairment varies, being severe or profound in advanced cases.

A good deal of attention has been directed to the surgical treatment of hydrocephalus, in which shunting devices are inserted to drain cerebrospinal fluid. With early diagnosis and treatment, this condition can usually be arrested before severe brain damage has occurred (Geisz & Steinhausen, 1974). Even with significant brain damage, carefully planned interventions that take into account both strengths and weaknesses in intellectual functioning show much promise (Baron & Goldberger, 1993).

## Cultural-Familial Mental Retardation

Investigators formerly believed that all mental retardation was the result of faulty genes or of other causes of brain impairment. In recent decades, however, it has become apparent that adverse sociocultural conditions, particularly those involving a deprivation of normal environmental stimulation, may play a primary role in the etiology of mental retardation. Two subtypes of mental retardation fall in this general category: (a) mental retardation associated with extreme sensory and social deprivation, such as prolonged isolation during the developmental years, as is occasionally inflicted on children by disturbed parents; and (b) **cultural-familial retardation,** in which a child is not subjected to extreme isolation but rather suffers from an inferior quality of interaction with the cultural environment and with other people. Because such sociocultural impoverishment

**Table 13.1** *Average IQs of 586 Milwaukee Children*

| Maternal IQ | Age of Children in Months | | | | | | |
|---|---|---|---|---|---|---|---|
| | 13–35 | 36–59 | 60–83 | 84–107 | 108–131 | 132–167 | 168+ |
| 80+ ($n = 48$) | 95 | 93 | 90 | 94 | 87.5 | 94 | 90 |
| < 80 ($n = 40$) | 95 | 76 | 84 | 80 | 75 | 70 | 67.5 |

From Garber (1988, p. 23)

may be associated with genetic deficiency in some cases, a child born to a family in such circumstances may be doubly jeopardized. In any event, it has proven all but impossible to assess the differential influences of nature and nurture in these cases.

Because most mental retardation is of the cultural-familial type, our discussion will focus on it. Consider Table 13.1 that depicts the average IQs of 586 Milwaukee children in differing age ranges. The children were separated according to whether or not the IQs of their mothers, all of whom dwelt in slum areas under deprived circumstances, fell below 80. Note that the two groups of children did not differ in IQ at ages 1 through 2 and that both scored within the normal range. The children whose mothers had IQs of 80 or above continued to manifest average IQs in the normal range through age 14. However, children of mothers of IQ less than 80 showed, on average, a progressive (and, after age 5, nonreversing) decline with advancing age that approached the upper limits of the mental retardation range by age 14. Such a progressive loss is not easy to reconcile with a hereditary interpretation; it suggests, rather, the cumulative effects of a deficient environment, one well indexed by the mothers' IQ levels.

Garber (1988) contends that the effect is due to the inadequacy of low IQ mothers in stimulating intellectual growth. Specifically, he maintains that the mothering person is normally responsible for creating the "microenvironment" determining a child's rate of cognitive development, and that a low maternal IQ—which is associated with verbal and other skill deficits—tends to foster an environment that is deficient in cognitively enriching experience. Although this conclusion is consistent with most available evidence, it would be tragic to convert such evidence to an assignment of blame against low-IQ women. They need help, not blame, and when they get this help, the IQs of their children may be substantially elevated (Garber, 1988; Ramey & Haskins, 1981; Turkheimer, 1991; Zigler & Muenchow, 1992; Zigler & Styfco, 1994).

Whatever the specific etiology, children whose retardation is cultural-familial in origin are usually only mildly retarded. They show no identifiable brain pathology and are usually not diagnosed as mentally retarded until they enter school and have difficulties with their studies. As many investigators have pointed out, most of these children come from economically deprived, unstable, and often disrupted family backgrounds characterized by a lack of intellectual stimulation, an inferior quality of interaction with others, and general environmental deprivation (e.g., Birns & Bridger, 1977; Braginsky & Braginsky, 1974; Feuerstein, 1977):

> They are raised in homes with absent fathers and with physically or emotionally unavailable mothers. During infancy they are not exposed to the same quality and quantity of tactile and kinesthetic stimulations as other children. Often they are left unattended in a crib or on the floor of the dwelling. Although there are noises, odors, and colors in the environment, the stimuli are not as organized as those found in middle-class and upper-class environments. For example, the number of words they hear is limited, with sentences brief and most commands carrying a negative connotation. (Tarjan & Eisenberg, 1972, p. 16)

Since a child's current level of intellectual functioning is based largely on previous learning—and since schoolwork requires complex skills, such as being able to control one's attention, follow instructions, and recognize the meaning of a considerable range of words—these children are at a disadvantage from the beginning because they have not had an opportunity to learn requisite background skills or to be motivated toward learning. Thus with each succeeding year, unless remedial measures are undertaken, they tend to fall further behind in school performance. They also fall further behind in relative ratings on intelligence tests, which, as we have seen, are measures of ability for schoolwork. A report by the American Psychological Association (1970) noted the following: "Mental retardation is primarily a psychosocial and psychoeducational problem—a deficit in adaptation to the demands and expectations of society evidenced by the individual's relative difficulty in learning, problem solving, adapting to new situations, and abstract thinking" (p. 267).

*The causal pattern in cultural-familial mental retardation is believed to include an impoverished and intellectually deprived developmental history.*

This statement was not intended to minimize the possible role of adverse biological factors, including genetic deficiencies, in the total causal pattern. Certainly many of these children reveal histories of prematurity, inadequate diet, and little or no medical care. In the great majority of cases of cultural-familial mental retardation, however, no neurological or physical dysfunction has been demonstrated. Thus, efforts to understand mild mental retardation have focused increasingly on the role of environmental factors in impeding intellectual growth. The likelihood that many of these factors will prove preventable or reversible has given rise to as yet incompletely realized hopes for effective, widespread intervention, as will be seen.

## The Problem of Assessment

Because mental retardation is defined in terms of both intellectual (academic) and social competence, it is essential to assess both of these characteristics before labeling a person mentally retarded. Unfortunately, neither of the preceding tasks is easy. Errors in IQ assessment can stem from a variety of sources, including (a) errors in administering and scoring tests; (b) the personal characteristics of a child, such as a language problem or lack of motivation to do well on tests; (c) temporary disrupting circumstances in the child's life, such as illness or family stress, and (d) limitations in the tests themselves.

Although the assessment of social competence may seem less complicated, especially if it is based on clinical observations and ratings, it is subject to many of the same errors as the measurement of IQ. In the elaborated version of adaptive skills assessment recently proposed by the AAMR (Luckasson et al., 1992), noted above, many of the skills included cannot be reliably measured with existing techniques (MacMillan et al., 1993). Also, the criteria used by the person or persons doing the assessing are of particular importance. For example, if children are well adapted socially to life in an urban ghetto but not to the demands of a formal school setting, should they be evaluated as having a high, intermediate, or low level of social competence? Competence for what? It is doubtful that judgments of this kind can be made objectively, that is, without reference to particular value orientations.

To label a child mentally retarded is likely to have profound effects on both the child's self-concept and the reactions of others, and thus on his or her entire future life. Most immediately, it may lead to a disadvantaged upbringing by discouraged, demoralized parents (Richardson, Koller, & Katz, 1985), to say nothing of the likely effects on overburdened schoolteachers. Over the long term, such a label may become a *self-fulfilling prophecy* fueled by the tendency to behave in ways consistent with one's self-concept and others' expectations. Obviously it is a label that has profound ethical and social implications; it should never be affixed to anyone without the most careful and considered judgment.

## Treatments, Outcomes, and Prevention

A number of programs have demonstrated that significant changes in adaptive capacity are possible through special education and other rehabilitative measures. The degree of change that can be expected is related, of course, to an individual's particular situation and level of mental retardation.

**Treatment Facilities and Methods** One problem that causes anxiety for the parents of a mentally retarded child is whether to put the child in an institution. In general, children who are institutionalized fall into two groups: (a) those who, in infancy and childhood, manifest severe mental retardation and associated physical impairment, and who enter an institution at an early age; and (b) those who have no physical impairments but show relatively mild mental retardation and a failure to adjust socially in adolescence, eventually being institutionalized chiefly because of delinquency or other problem behavior (see Stattin & Klackenberg-Larsson, 1993). In these cases, social incompetence is the main factor in the decision. The families of those in the first group come from all socioeconomic levels, whereas a significantly higher percentage of the families of those in the second group come from lower educational and occupational strata.

The effect of being institutionalized in adolescence depends heavily, of course, on an institution's facilities as well as on individual factors. For the many retarded teenagers who do not have families in a position to take care of them, community-oriented residential care seems particularly promising (Alexander, Huganir, & Zigler, 1985; Landesman-Dwyer, 1981; Seidl, 1974; Thacher, 1978), although for maximum effectiveness great care must be taken in adequately assessing needs and in the recruitment of staff personnel (Petronko, Harris, & Kormann, 1994).

For the mentally retarded who do not require institutionalization, educational and training facilities have historically been woefully inadequate. It still appears that a very substantial proportion of mentally retarded people in the United States are never reached by services appropriate to their specific needs (Luckasson et al., 1992; Tyor & Bell, 1984).

This neglect is especially tragic in view of what we now know about helping these people. For example, classes for the mildly retarded, which usually emphasize reading and other basic school subjects, budgeting and money matters, and the development of occupational skills, have succeeded in helping many people become independent, productive community members. Classes for the moderately and severely retarded usually have more limited objectives, but they emphasize the development of self-care and other skills that enable individuals to function adequately and to be of assistance in either a family or institutional setting. Just mastering toilet training and learning to eat and dress properly may mean the difference between remaining at home and being placed elsewhere.

Today there are only some 80,000 individuals still in institutions for the retarded, roughly half the number that were residents a mere 25 years ago. Even many of these more seriously affected persons are being helped to be partly self-supporting in community programs (Brown, 1977; Landesman-Dwyer, 1981; McDonnell et al., 1993; Robinson & Robinson, 1976; Thacher, 1978). These developments reflect both the new optimism that has come to prevail and also, in many instances, new laws and judicial decisions favorable to the rights of retarded people and their families. A notable example is Public Law 94-142, passed by Congress in 1975. This statute, termed the Education for All Handicapped Children Act, asserts the right of mentally retarded people to be educated at public expense in "the least restrictive environment" possible.

During the 1970s, there was a rapid increase in alternate forms of care for the mentally retarded (Tyor & Bell, 1984). These included, but were not limited to, the use of decentralized regional facilities for short-term evaluation and training; small private hospitals specializing in rehabilitative techniques; group homes or "halfway houses" integrated into the local community; nursing homes for the elderly retarded; the placement of severely retarded children in more "enriched" foster-home environments; and varied forms of support to the family for own-home care. The last quarter century, in short, has seen a marked enhancement of alternative modes of dealing with retarded citizens, rendering obsolete many public institutions formerly devoted exclusively to this type of care.

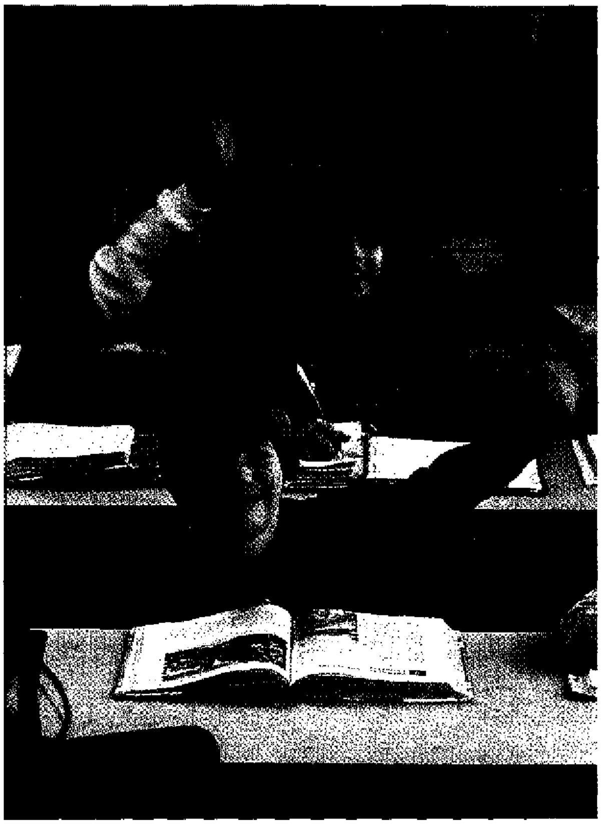
Although much remains to be learned about the most effective educational and training procedures to use with the mentally retarded—particularly the moderate and severe types—new techniques, materials, and specially trained teachers have produced encouraging results. For example, computer-assisted instruction has been found to be more efficient as well as less expensive than traditional tutor-guided instruction (Brebner, Hallworth, & Brown, 1977; Hallworth, 1977). New uses for the computer in this field are developing at a rapid rate (Lovett, 1985). Operant-conditioning methods are being used increasingly to teach a wide variety of skills (Kiernan, 1985). Specifically targeted independence training in various everyday functions (Matson, 1981) obviously has great promise. A technique for teaching improved thinking skills, developed by Reuven Feuerstein in Israel, has been extensively evaluated and produces substantial, though not spectacular, improvements in cognitive functioning (e.g., Arbitman-Smith, Haywood, & Bransford, 1984).

Typically, educational and training procedures involve mapping out target areas of improvement, such as personal grooming, social behavior, basic academic skills, and (for retarded adults) simple occupational skills (see Forness & Kavale, 1993). Within each area, specific skills are divided into simple components that can be learned and reinforced before more complex behaviors are required. Training that builds on step-by-step progression can bring retarded individuals repeated experiences of success and lead to substantial progress even by those previously regarded as uneducable (see McDonnell et al., 1993).

For mildly retarded youngsters, the question of what schooling is best is likely to challenge both parents and school officials. For many years, organized parents' groups have fought an uphill battle to ensure the availability of special education classes for retarded children in the public schools, having learned that isolation from peers tends to compound the problem. Too often, however, success in getting a retarded child into a public school has meant that the child is treated as very special indeed and—along with other retarded students—becomes isolated within the school. We have now learned that this type of "special" education may have serious limitations in terms of a child's social and educational development, and that many such children fare better by attending regular classes for at least much of the day. Of course, this type of approach—called **mainstreaming**—does require careful planning, a high level of teacher skill, and facilitative teacher attitudes (Birns & Bridger, 1977; Borg & Ascione, 1982; Budoff, 1977; Hanrahan, Goodman, & Rapagna, 1990; Kozleski & Jackson, 1993; Stafford & Green, 1993).

Substantial research has led to the conclusion that mainstreaming is not the hoped-for panacea for retarded children (Gottlieb, 1981). Such programs are difficult to launch and to maintain (Lieberman, 1982); their success (or lack of it) seems to depend largely on such change-resistant influences as teacher attitudes and overall classroom climate (Haywood, Meyers, & Switsky, 1982; Miller, 1989; Schumm & Vaughn, 1992). Moreover, any educational gains may come at the expense of deficits in self-esteem suffered by handicapped children as they interact intensively with more cognitively advantaged peers (Haywood et al., 1982). Gresham (1982) argues that such dangers may be decreased or eliminated if retarded children are given social skills training before they enter a mainstream classroom. Also, when the situation is sensitively managed, the normal classmates of mainstreamed children may themselves derive benefits from the experience (Lincoln et al., 1992). A variant of mainstreaming called the Parallel Alternate Curriculum program, which emphasizes specialized instruction in a regular classroom setting, has shown much promise. Even here, however, much attention must be given to teaching-staff development (Chandler, 1985; Smith & Smith, 1985).

A reasonable conclusion at this time is that school systems should not attempt mainstreaming without a great deal of advance planning and preparation. In other words, mere window dressing to achieve an appearance of progressive educational practice is not enough; the system's leadership must be thoroughly committed to overcoming deeply entrenched attitudes and procedures within the education bureaucracy to ensure the success of the effort.



*The mainstreaming of mildly retarded children into regular classes for much of the day requires careful planning and a high level of teacher skill and facilitative teacher attitudes.*

**Frontiers in Prevention** More than three decades ago, President John F. Kennedy had the following to say about mental retardation:

> Studies have demonstrated that large numbers of children in urban and rural slums, including preschool children, lack the stimulus necessary for proper development in their intelligence. Even when there is no organic impairment, prolonged neglect and a lack of stimulus and opportunity for learning can result in the failure of young minds to develop. Other studies have shown that, if proper opportunities for learning are provided early enough, many of these deprived children can and will learn and achieve as much as children from more favored neighborhoods. The self-perpetuating intellectual blight should not be allowed to continue. (1963, p. 286)

President Kennedy's remarks are as valid and relevant today as they were when first issued. He may, however, have underestimated the difficulties of the task. In addition, much change in the body politic has occurred in the interim, not all of it supportive of the widespread social changes he advocated.

Perhaps the most important surviving element of that 1960s era in the area of mental retardation has involved efforts to reach high-risk children early with the intensive cognitive stimulation believed to underlie the sound development of mental ability. Project Head Start is a well-known example operating at the local community level, one whose effectiveness is difficult to measure and therefore subject to controversy (Gamble & Zigler, 1989). In fact, however, local Head Start programs have varied widely in their organizational and management expertise and in their commitment to making a difference in the lives of their child clientele. Perhaps inevitably, too, politics and bureaucratic bumbling have often served to dull the cutting edge Head Start was fashioned to provide (Zigler & Muenchow, 1992). In the end, no program of early intervention can guarantee a successful outcome. Nevertheless, the available outcome data are clear in showing that well-managed Head Start programs have amassed a very creditable record in launching children on the path to educational and occupational accomplishment; considering the stakes in failed and socially costly lives, they appear to be an excellent community investment (Zigler & Styfco, 1994).

At the national level, a similar intention has inspired specialized television programming for children, such as *Sesame Street* and *Reading Rainbow*. Rigorous assessment of the effectiveness of such efforts has never been satisfactorily completed, but they do appear to have positive effects on many children. Ironically, the children who seem to benefit most from these efforts are the children least in need of them—the children of relatively affluent families in which education is strongly valued and in which the parents are likely to encourage their children to watch enriching television programming.

Also somewhat sobering is the possibility that the educational performance of many Head Start children increases primarily because of temporarily enhanced motivation rather than higher rates of cognitive development (Zigler et al., 1982). Where the environment continues to be harmful over time, the gain for many youngsters exposed to short-term enrichment programs may be lost (Garber, 1988; Gray & Ramsey, 1982). Obviously, much remains to be learned and done in the area of maintaining early gains. Where notable and sustainable gains have not been unequivocally demonstrated, the necessary financial investment may attract the kind of short-sighted political opposition commonly directed at expensive "social" programs (see Chafel, 1992). The irony is that the money is spent anyway, usually at compounded rates of increase, on such things as ADC (welfare-based aid to dependent children), chronic institutionalization, correctional facilities, and the "war on drugs."

The federal initiatives begun by the Kennedy administration have eroded over the years. Demands on the federal budget for programs seen as having greater national priority have increased, and the funds committed for helping the retarded have suffered devaluation through inflation. Beginning with the Nixon administration of the early 1970s, serious cutbacks were made in training and research in all of the mental health disciplines. The trend has become worse since that time as the national debt has increased to unprecedented levels and as many states have likewise experienced severe fiscal problems. As a result, we have not been able to capitalize fully on our increased understanding of how to reverse or prevent the deficits experienced by mentally retarded youngsters and adults.

## SPECIFIC LEARNING DISORDERS

In contrast to generalized developmental disorders such as mental retardation and autism (addressed in Chapter 14), **specific learning disorders** have a circumscribed character and may occur in children who are otherwise normal or even gifted in their overall functioning. The inadequate development may be manifested in academic, language, speech, or motor-skills areas, and it is not due to any demonstrable physical or neurological defect. The diagnosis is restricted to those cases in which there is clear impairment in school performance or (if the person is not a student) in daily living activities, not due to mental retardation or a "pervasive developmental disorder," such as autism. Skill deficits due to attention-deficit hyperactivity disorder, described in Chapter 14, are coded under that diagnosis. This coding presents another diagnostic dilemma because some investigators hold that an attentional deficit is basic to many learning disorders; evidence for the latter view is equivocal (see Faraone et al., 1993). We will focus in this section on specific developmental disorders involving academic skills, also known as specific learning disabilities, or—in DSM-IV terms—simply learning disorders (formerly academic skills disorders). Children with these disorders are more generally said to be *learning disabled* (LD). Significantly more boys than girls are diagnosed as learning disabled, but proportional estimates of this gender discrepancy have varied widely from study to study.

## The Clinical Picture in Learning Disorders

Learning disabled children are identified as such because of a disparity between their expected academic achievement level and their actual academic performance in one or more school subjects, such as math, spelling, writing, or reading. (Reading problems are commonly known as ***dyslexia***.) Typically, these children have IQs, family backgrounds, and exposure to cultural norms and symbols that are consistent with at least average achievement in school. They do not have obvious crippling emotional problems, nor do they seem to be lacking in motivation, cooperativeness, or eagerness to please their teachers and parents—at least not at the outset of their formal education. Nevertheless, they fail, often abysmally and usually with a stubborn, puzzling persistence. Why? As we will see, satisfactory answers are hard to come by.

Frustration for teachers, school officials, parents, professional helpers, and perhaps most notably for the victims themselves (although the last may go unnoticed in the general turmoil) is virtually guaranteed in this scenario, and it is likely to complicate efforts to find a solution. Wenar (1990) poignantly depicts the problem:

> You are a child clinical psychologist. It has been a rough day. The climax was a phone call to the principal of Wykwyre Junior High School. It is the kind of suburban school in which children from two-swimming-pool families do not speak to children from one-swimming-pool families. The call had been about Jon Hastings, a 16-year-old with a long history of school failures. The intelligence test showed him to be bright enough to do college work, and yet he is only in the eighth grade. He is articulate, has a talent for making miniature rockets and speedboats, and a real flair for drawing cartoons. Yet the written word is Jon's nemesis. He reads laboriously one word at a time, while his writing is even more painfully slow. Because of repeated failures and because he is now a social misfit with peers, he has begun cutting up in class and talking back to the teacher.
>
> You had phoned the principal to suggest ways of bypassing Jon's reading disability. Since he is sufficiently bright to absorb most of the lecture material, could he be given oral examinations every now and then? If he were taught to type, could he type instead of writing his examinations? Would the principal consider introducing special classes for all the learning-disabled children?
>
> The principal was suave and ingratiating and a compendium of the resistances you have run up against in the past. He "understood your concern" but asked that you "look at the situation from my point of view." The school had "tried everything possible to no avail," "the boy is incorrigible," "you can't help a child unless the child wants help," and finally—you could feel this one coming, since you had heard it so often—"I can't give one student a favor without giving a favor to all of them. I'd have half the mothers in my office next day demanding something extra to pull their child's grades up." (p. 197)

It is unfortunately the case that LD, despite its having been recognized as a distinct and rather common type of disorder for more than 35 years, and despite its having generated a voluminous research literature, still fails to be given the status it deserves in many school jurisdictions. Instead, as in the preceding example, the familiar diversion of blaming the victim and of attributing the affected child's problems to various character deficiencies is still routinely employed by many classroom teachers and school administrators, whether in public or private settings (see Fischer, 1993; Moats & Lyon, 1993). Where lockstep uniformity is the rule, as it is in most public and many "alternative" educational systems, a youngster who learns academic skills slowly or in a different way is treated as a troublemaker, as a threat to the prevailing theory of education. The consequences of these encounters between LD children and rigidly doctrinaire or regimented school systems can be disastrous to a child's self-esteem and general psychological well-being, and research indicates that these effects do not necessarily dissipate after secondary schooling ends (Brinckerhoff, 1993; Bruck, 1987; Saracoglu, Minden, & Wilchesky, 1989; Walters & Croen, 1993; Wilczenski, 1993). Thus even where LD difficulties are no longer a significant impediment, an individual may bear the scars of many painful school-related episodes of failure into maturity and beyond.

## Causal Factors in Learning Disorders

Probably the most generally held view of the cause of specific learning disabilities is that they are the products of subtle central nervous system impairments. In particular, these disabilities are thought to result from some sort of immaturity, defect, or dysregulation limited to those brain areas supposedly mediating, for normal children, the cognitive skills and/or behaviors that LD children cannot efficiently acquire. A few years back the term ***minimal brain dysfunction*** (MBD) was in popular use to refer to such presumed organic malfunction—until it was generally recognized that nobody had the slightest idea what the term really meant. While some LD children show definite or highly suggestive evidence of brain disease, such as cerebral palsy, epilepsy, or a history of severe head trauma (e.g., Yule & Rutter, 1985), the large majority do not. In others, there may be subtle indications, "soft signs," of neurological compromise, but again such findings are by no means routine. Overall, there is no convincing evidence of a specific central nervous system dysfunction among LD children generally (Durrant, 1994; Schwartz & Johnson, 1985). The search for such factors has lessened in recent years, possibly because investigators have become discouraged by the meager findings thus far.

A variant of the central nervous system dysfunction hypothesis proposes some type of defect or imbalance in the brain's normal laterality—that is, in the tendency for specific functions to be localized to a large extent in either the right or the left side of the brain. Studies in this area, mainly concerned with dyslexia, have failed to produce a consistent or coherent set of findings (Kessler, 1988). They have also been plagued with many methodological shortcomings (Durrant, 1994; Hynd & Semrud-Clikeman, 1989).

Some investigators believe that the various forms of LD, or vulnerability to develop them, may be genetically transmitted. This issue seems not to have been studied with the same intensity or methodologic rigor as in other disorders. Two family pedigree studies, those of Hallgren (1950) and Finucci and colleagues (1976), showed evidence of familial concordance for "reading disorders" (dyslexia), and Owen (1978) cites a twin study in which monozygocity was associated with 100 percent concordance for reading disorders. Very recently, identification of a gene region for dyslexia on chromosome 6 has been reported, although the specific gene implicated has not yet been determined (*Science News*, October 22, 1994, p. 271). Although it would be somewhat surprising if a single gene were to be identified as the causal factor in all cases of reading disorder, the hypothesis of a genetic contribution to at least the dyslexic form of LD appears increasingly promising.

Summing up, biological or organic hypotheses concerning the etiology of LD, though widely held, tend to be vague on mechanisms and—excepting dyslexia—do not have an exceptionally strong record of evidence supporting them. They continue to have a sort of intuitive appeal that is at least as great as alternative psychosocial theories of causation.

*Dyslexia is a learning disability that interferes with the ability to read and write. This dyslexic student is transposing letters and writing other letters backward. Learning disabled children, frustrated by their academic failures, may become social failures as well. If undiagnosed, these children may be seen by school authorities as troublesome and intractable, thus compounding their problems and further damaging their self-esteem. The long-term academic, social, and personal adjustment for those who grew up with undiagnosed dyslexia is generally discouraging, but there are important exceptions.*

Psychosocially based hypotheses about the origins of LD generally derive from psychodynamic, learning, or cognitive perspectives, or a combination of them. To date, none of them has sufficient empirical support to warrant extended discussion. The apparent complexity of the psychological processes involved in LD (see Ceci & Baker, 1987) evidently makes it difficult to do definitive studies on potential causal factors. Thus the research that is available, most of it again directed to the problem of dyslexia, tends to be riddled with problems of subject selection, inappropriate controls, and other serious methodological flaws (Durrant, 1994; Vellutino, 1987).

Despite what appears to be a multitude of seemingly differing factors involved in LD, there may yet be some common elements. This is the position taken by Worden (1986), who argues that we should study what characterizes the approaches taken by good learners to be able to identify the areas of significant weakness from which LD children suffer. He offers the following list as a beginning in this direction:

1. What memory strategies are used by normal or good learners, and in what manner do these differ from those employed by LD children?

2. How do normal or good learners monitor their ongoing performances? For example, how do good learners use performance information to gauge where they are being successful and where not, and to introduce corrective action as needed?

3. What metastrategy information is used by good learners and not by LD children? For example, do LD children understand the advantage of having a strategy at all, as in dealing with the time constraints of many school tasks?

4. What motivates good learners, and how does this differ from the motivation of poor learners? Is a learner's orientation one of seeking success or of avoiding failure? To what is success or failure attributed: oneself, task difficulty, chance, or some other factor?

Worden's approach to analyzing the complex issues involved in academic skill acquisition strikes us as a potentially useful beginning. However, even precise information on the manner in which LD children's learning approaches differ from those of normal children would still leave us with unanswered questions about the sources of these differences. Nevertheless, pursuit of this idea might produce a set of rational, fine-tuned strategies for intervening to correct LD children's inefficient modes of learning. We are not aware of any follow-up studies along this line.

## Treatments and Outcomes

Because we do not yet have a confident grasp on what is "wrong" with the average LD child, we have had limited success in treating these children. While many informal and single-case reports claim success for various treatment approaches, there are few well-designed and well-executed outcome studies on specific treatments for LD problems. Focusing on reading disorders, where most of the effort has been concentrated, Gittelman's (1983) review contains little evidence of impressive results. Moreover, any short-term gains that are made tend in many cases to diminish or even disappear over time (Yule & Rutter, 1985).

Recently, Ellis (1993) has offered a comprehensive intervention model to facilitate learning in LD, called Integrative Strategy Instruction (ISI), that has inspired considerable interest among professionals in the field (see Houck, 1993; Hutchinson, 1993; Parker, 1993; Walsh, 1993). Organized according to particular content areas, it envisions a variety of teacher-directed instructional strategies directed at key aspects of the learning process: orienting, framing, applying, and extending. Although the model is too new to have been tested empirically for efficacy, its knowledge-based and systematic character is a welcome addition to the analysis of the educational problems presented by LD children. Its application would seem to demand, however, high levels of administrative flexibility and teacher skill, neither of which can be taken for granted in the average school environment (see Hutchinson, 1993; Parker, 1993).

It is encouraging that increasing efforts are being made to identify and provide services for LD students in higher education settings. Many of these students are sufficiently bright and resourceful to circumvent lower-level educational barriers to find themselves confronted with challenges requiring skills they simply do not have. Walters and Croen (1993), for example, describe such efforts in a medical school environment; they stress the need for early identification, provision of appropriate support, and arranging minimal accommodations for medical students having LD problems. Yanok (1993) describes an apparently successful "developmental education program" for LD college students, thus providing for these individuals an "equal educational opportunity."

We have only limited data on the long-term, adult adjustments of people who grew up with the personal, academic, and social problems LD generally entails. Two studies of college students with LD (Gregg & Hoy, 1989; Saracoglu et al., 1989) suggested that as a group they continue to have problems—academic, personal, and social—into the postsecondary education years. Cato and Rice (1982) extracted from the available literature a lengthy list of somewhat discouraging problems experienced by the typical LD adult. These include—in addition to expected difficulties with self-confidence—continuing problems with deficits in the ordinary skills, such as math, that these people originally encountered as children. The authors did note, however, that there are considerable individual differences in these outcomes, thus reminding us that some adults with LD are able to manage very well.

## UNRESOLVED ISSUES
## on Cultural-Familial Retardation

The problem of cultural-familial mental retardation continues to be a baffling and frustrating one—complicated in no small measure by sensitive issues of race relations and imputed ethnic differences in native abilities. No scientifically respectable evidence suggests that the quality of brain tissue is in any degree correlated with race or ethnicity. A great deal of evidence, on the other hand, shows that different ethnic groups, on average, vary considerably in performance on standardized tests designed to predict academic achievement. The very controversial book *The Bell Curve* (Herrnstein & Murray, 1994) contains the most recent comprehensive discussion of such intergroup differences in average IQ test scores. Unfortunately, we have long been encouraged to regard such tests as more or less directly measuring "intelligence," which they do not—unless one is willing to accept school grades as the primary defining element of that construct. IQ tests are and have always been validated primarily on their ability to predict school performance.

Schools may reasonably be viewed as having the principal function of transmitting a culture's approved products from earlier to later generations; approved products are those deemed valuable by a cultural elite. So-called intelligence tests, then, are designed to measure the facility with which a child may be expected to acquire and adequately process what the school offers. It does not seem farfetched to suggest that a child's performance in school will be determined to a considerable extent by the amount of prior and continuing extracurricular exposure he or she has to the products of the dominant culture that the school represents. Indeed, we have a fair amount of empirical evidence showing that this is so. We also have a fair amount of empirical evidence suggesting that a person's IQ ("intelligence" quotient) rises significantly with enhanced exposure to these cultural products. It is therefore more than a mere possibility that what IQ tests mostly measure is prior exposure to approved cultural products. Considered from this perspective, the notion of a "culture-free" IQ test that would also do well at predicting school grades is a practical impossibility.

The fact that African Americans in the United States are disproportionately represented among those labeled "retarded" is clearly related to the prominence of the IQ measure in the definition of retardation. African Americans have a persistent 15-point deficit, on average, relative to whites on this type of test. However interpreted—whether in terms of "test bias" or in terms of a "real" difference (and from the preceding argument we suggest that these are the same things)—one implication seems clear. Namely, African Americans as a group are seriously disadvantaged in engagements with the standard educational system. Relative success in such engagements, as already noted, is mostly what IQ tests are designed to predict, and for the most part they do so effectively. If, as is often said (we have our own small doubts), conventional academic success leads to such happiness and riches as are attainable in our larger culture, then enormously disproportionate numbers of African Americans will continue to be excluded from the good life unless some remedy for this problem can be found.

As we have seen, serious and broad-based efforts to find a remedy were begun in the 1960s, Project Head Start being a notable example. Much was learned in the programs that were launched during that era, one of the most important lessons being that genuine and sustained advance was costly and difficult. For example, we learned that the gains in academic skill acquired in an enriched preschool experience, as in Head Start, were not lasting without a more general environmental enrichment. However, subsequent changes in national priorities and in the political atmosphere, particularly at the federal level, precluded a vigorous follow-up of these initiatives. We have not regained momentum in this area, nor does it appear likely, as of this writing, that we soon will. If progress in laying to rest the cold war and in the achievement of "the new world order" were happily to continue, however, sufficient funds and energies might be liberated to contemplate seriously a new national order, one in which all of our children might truly be granted equal opportunity. It is a cruel deception, in our judgment, to suggest that they have it now.

## SUMMARY

The neuropsychological mental disorders are those in which mental symptoms of a neurologic or psychopathologic sort (such as cognitive deterioration and delusions, respectively) are presumed to appear as a result of malfunction of the brain's "hardware," typically involving the destruction of brain tissue. Generally, these disorders are in some primary sense physical diseases and are accordingly coded on Axis III of DSM-IV, in addition to a descriptive Axis I coding that pertains to the nature of the mental symptoms manifested. The current DSM recognizes certain characteristic neuropsychological syndromes that form a basis for an Axis I psychiatric diagnosis where the precise organic etiology is unknown or is implied in an accompanying Axis III disease; those discussed here are delirium, dementia, amnestic syndrome, and neuropsychological delusional, mood, and personality syndromes. These syndromes are conceived as the primary behavioral indicators for organic brain disease. Some of them mimic disorders in which no gross brain pathology can be demonstrated, which may present problems in diagnosis.

Neuropsychological disorders may be acute and transitory; in this case, brain functioning is only temporarily compromised. Chronic neuropsychological disorders, on which we have focused, involve the permanent loss of neural cells. Psychosocial interventions are often helpful in minimizing psychopathologic reactions in the chronically disordered, although these people will remain neurologically disabled.

The primary causes of brain tissue destruction are many and varied; common ones include certain infectious diseases (such as the HIV-1 virus), brain tumors, physical trauma, degenerative processes (as in Alzheimer's disease), and cerebrovascular arteriosclerosis, often manifested as vascular dementia. The correlation between neurologic brain impairment and psychiatric disorder, however, is not an especially strong one: Some people who have severe damage develop no severe mental symptoms, while others with slight damage have extreme reactions. Although such inconsistencies are not completely understood, it appears that an individual's premorbid personality and life situation are also important in determining his or her reactions to brain damage.

Elderly people are at particular risk for the development of chronic organic mental disorders, especially those related to brain degeneration caused by Alzheimer's disease. As at younger ages, the reaction to brain damage is determined by many nonbiological factors. With disproportionate increases in the numbers of elderly people in the population, and the upcoming wave of baby boomers who will become at risk beginning early in the twenty-first century, we face staggering social, emotional, and economic problems unless some way can be found to prevent or effectively treat Alzheimer's disease.

When serious organic brain impairment occurs before the age of 18, and especially where it is congenital or is acquired shortly after birth, the cognitive and behavioral deficits experienced are referred to as mental retardation. Relatively common forms of such mental retardation, which in these cases is normally at least moderate in severity, include Down syndrome, phenylketonuria (PKU), and certain cranial anomalies. This organic type of mental deficit accounts for only some 25 percent of all cases of mental retardation. Mental retardation diagnoses, regardless of the underlying origins of the deficit condition, are always coded on Axis II of DSM-IV.

The large majority—some 75 percent—of mental retardation cases are unrelated to obvious physical defects and are considered cultural-familial in origin, a term that acknowledges our inability to disentangle genetic and environmental influences in the disorder. Caution is warranted in applying the label "mentally retarded," in part because of the heavy reliance on IQ test scores in its definition. The IQ test is—and always has been—a measure of academic skill, not of ability to survive and perhaps even prosper in other areas of life. A variety of evidence points to the conclusion that cultural-familial retardation may be treatable and even preventable, provided we can find the means of providing the necessary cognitive stimulation to socially and economically deprived children.

Specific learning disorders are those in which failure of mastery is limited to circumscribed areas, chiefly involving academic skills such as reading; general cognitive ability may be normal or superior. Affected children are commonly described as learning disabled (LD). Here again some localized defect in brain development is usually considered the primary cause, although independent corroboration of an organic cause is the exception rather than the rule. These disorders create great turmoil and frustration in victims, their families, schools, and professional helpers. Various remedies, most involving training regimens of one sort or another, are tried and apparently are sometimes successful. However, solid outcome research in the area of intervention techniques is seriously lacking. The long-term prognosis for LD, overall, is not particularly encouraging.

# DISORDERS OF CHILDHOOD AND ADOLESCENCE

---

*Dwight Mackintosh,* My Mother Baking Bread. *Mackintosh (b. 1906), a native of California, was admitted into a mental institution at the age of 16 after having become "unmanageable at home." He remained in state mental hospitals until the deinstitutionalization movement inspired his release in 1978. His brother, Earl, remembered that Dwight had been interested in art as a boy and took him to the Creative Growth Art Center in Oakland, California, where he began to draw and paint earnestly. People are the primary subject of his art, and drawing his only way of expressing his interest in them; otherwise, he is deeply withdrawn.*

UNRESOLVED ISSUES ON PARENTAL PATHOLOGY AND CHILDHOOD AND ADOLESCENT DISORDERS

SUMMARY

KEY TERMS

During the nineteenth century, little account was taken of the special characteristics of psychopathology in children; maladaptive patterns that are considered relatively specific to childhood, such as autism, received virtually no attention at all. Since the turn of the twentieth century, with the advent of the mental health movement and the availability of child guidance facilities, marked strides have been made in assessing, treating, and understanding the maladaptive behavior patterns of children and adolescents. This progress has, however, lagged behind efforts to deal with adult psychopathology. In fact, as we will see, early efforts at classifying problems of childhood were simply downward extensions of adult-oriented diagnostic systems.

These early conceptualizations seemed to reflect a prevailing view of children as "miniature adults" and failed to take into account special problems, such as those associated with the developmental changes that normally take place in a child or adolescent. Only recently have we come to realize that we cannot fully understand childhood disorders without taking into account these developmental processes; in fact, the field is often referred to as **developmental psychopathology.** Today, even though great progress has been made in providing treatment for disturbed children, our facilities are woefully inadequate in relation to the magnitude of the task, and most problem children do not receive psychological attention (Links, Boyle, & Offord, 1989). The numbers of children affected by psychological problems are considerable. For example, recent studies (Brandenberg et al., 1990; and the Office of Technology Assessment, 1986) suggest that as many as 12–15 percent of American children have psychological disorders.

Recent multisite studies in several countries have provided estimates of childhood disorder that range from 17 to 22 percent (Costello, 1989; Institute of Medicine, 1989; Verhulst & Koot, 1992; and Zill & Schoenborn, 1990). In most studies, maladjustment is found more commonly among boys than among girls. In one survey of psychological disorder in children, Anderson and colleagues (1987) found that 17.6 percent of 11-year-old children studied had one or more disorders. Boys were diagnosed more frequently than girls at 1.7 to 1. The most prevalent disorders were attention-deficit hyperactivity disorder and separation anxiety disorders. More recently, Zill and Schoenborn (1990) reported that rates of childhood disorders varied by gender with boys having higher rates of emotional problems over the childhood and adolescent years. However, for some diagnostic problems rates for girls are higher than for boys.

In the first section of this chapter we will note some general characteristics of maladaptive behavior in children compared with adult disorders. Next we will examine the issues surrounding the diagnostic classification of children's disorders. Then we will look at a number of important disorders of childhood and adolescence. In the final section we will give detailed consideration to some of the special factors involved in both the treatment and prevention of children's problems.

## MALADAPTIVE BEHAVIOR IN DIFFERENT LIFE PERIODS

Because personality differentiation, developmental tasks, and typical stressors differ in childhood, adolescence, and adulthood, we would expect to find some differences in maladaptive behavior in these periods. The special characteristics of childhood disorders are discussed here.

### Varying Clinical Pictures

The clinical picture in childhood disorders tends to be distinct from those of other life periods. Some of the emotional disturbances of childhood may be relatively short-lived, undifferentiated, and changeable compared with those of later life (Lewis et al., 1988). It should be kept in mind, however, that some childhood disorders severely affect future development. One study found that individuals who had been hospitalized as child psychiatric patients (between the ages of 5 and 17) showed excess mortality in unnatural deaths (about twice the rate of the general population) when followed up from 4 to 15 years later (Kuperman, Black, & Burns, 1988). Suicide accounted for most of these deaths, and the suicide rate was significantly greater than in the general population.

### Special Vulnerabilities of Young Children

Young children do not have as complex and realistic a view of themselves and their world as they will have at a later age. They have less self-understanding and have not yet developed a stable sense of identity and an adequate frame of reference regarding reality, possibility, and value. Immediately perceived threats are tempered less by considerations of the past or future and thus tend to be seen as disproportionately important. As a result, children often have more difficulty in coping with stressful events than do adults (Compas & Epping, 1993; Kepel-Benson & Ollendick, 1993). A follow-up study of young victims of the Buffalo Creek flood, for example, found that children are at risk of posttraumatic stress disorder after a disaster, especially if the family atmosphere is troubled (Green et al., 1991) (see HIGHLIGHT 14.1).

Children's limited perspectives, as might be expected, lead them to use unrealistic concepts to explain events. For example, a child who commits suicide may be trying to rejoin a dead parent, sibling, or pet. For young children, suicide—or violence against another person—may be undertaken without any real understanding that death is final.

Children also are more dependent on other people than are adults. Though in some ways this dependency serves as a buffer against other dangers, it also makes them highly vulnerable to experiences of rejection, disappointment, and failure. On the other hand, although their inexperience and lack of self-sufficiency make them easily upset by problems that seem minor to the average adult, children typically recover more quickly from their hurts. Moreover, many problematic behaviors and threats to adjustment emerge over the course of *normal* development (Kazdin, 1992). Indeed, several behaviors that characterize maladjustment or emotional disturbance are relatively common in childhood. It is imperative that we view a child's behavior in reference to normal childhood development. We cannot understand or consider as "abnormal" a child's behavior without considering whether the behavior in question is appropriate for the child's age. Behavior such as temper tantrums or eating inedible objects might be viewed as symptoms of abnormal behavior at age ten but not at age two. Despite the somewhat distinctive characteristics of childhood disturbances at different ages, there is no sharp line of demarcation between the maladaptive behavior patterns of childhood and those of adolescence, nor between those of adolescence and those of adulthood. Thus, although our focus in this chapter will be on the behavior disorders of children and adolescents, we will find some inevitable overlap with those of later life periods. In this context, it is useful to emphasize the basic continuity of a person's behavior over time.

## THE CLASSIFICATION OF CHILDHOOD AND ADOLESCENT DISORDERS

Diagnosis of the psychological disorders of childhood has traditionally been a rather confused practice, and until the 1950s no formal, specific system was available for classifying the emotional problems of children and adolescents. Kraepelin's (1883) classic textbook on the classification of mental disorders did not include childhood disorders. Not until

1952, when the first formal psychiatric nomenclature (DSM-I) was published, was a classification system for childhood disorders made available. The DSM-I system, however, was quite limited and included only two childhood emotional disorders: childhood schizophrenia and adjustment reaction of childhood. In 1966, the Group for the Advancement of Psychiatry provided a classification system for children that was detailed and comprehensive. In the 1968 revision of the DSM (DSM-II) several additional categories were included. A growing concern remained, however, both among clinicians attempting to diagnose and treat childhood problems and among researchers attempting to broaden our understanding of childhood psychopathology, that the then-current ways of viewing psychological disorders in children and adolescents were inappropriate and inaccurate for several reasons. The greatest problem stemmed from the fact that the same classification system that had been developed for adults was used for childhood problems. Many disorders such as autism, learning disabilities, and school phobias have no counterpart in adult psychopathology. Second, the early systems ignored the fact that in childhood disorders, environmental factors play an important part in the expression of symptoms; that is, symptoms are highly influenced by a family's acceptance or rejection of the behavior. For example, either extreme tolerance of deviant behavior or total rejection and neglect could lead a child's extreme behavior to be viewed as "normal." Third, symptoms were not considered with respect to a child's

14.1

## Psychological Adjustment Problems of Children in Disasters

Children are particularly vulnerable to highly stressful situations following in the wake of a disaster such as a hurricane, automobile accident, or the loss of an immediate family member. In the aftermath of a disaster, many children show increased specific disaster-related fears, increased dependence on adults, problems with separating from adults in their environment, sleeping difficulties, irritability, and often regressed behavior such as bedwetting or soiling (Saylor, 1993; Vogel & Vogel, 1993). As described in Chapter 4, the symptoms of posttraumatic stress disorder in children often persist months after the disaster has occurred (Swenson et al., 1991).

Some disaster situations are likely to be more upsetting to children than others. For example, children are more likely to become distressed in situations that involve life-threatening events or those in which a close family member dies or is seriously injured. Additionally, some children are more vulnerable to psychological problems following a disaster than others. For example, younger children appear to be more vulnerable to experiencing posttraumatic stress than older children, and girls tend to report more overall posttraumatic symptoms such as anxiety and depression than do boys.

The special problems that children face in disasters require thoughtful preparation and timely intervention if long-term problems are going to be averted. An effective program for dealing with children's problems in disasters was described by Vogel and Venberg (1993). This four-phase model describes strategies for managing children's adjustment difficulties in a disaster through several strategies:

1. ***Predisaster preparation is important to organize services to the community for effective response to potential disaster.*** Predisaster preparation includes the development of a disaster response network to respond to children's needs in the event of a disaster, particularly if one is imminent.
2. ***Intervention close to the disaster impact is crucial*** (Joyner & Swenson, 1993). Initial interventions after a disaster involve mounting efforts to help children during the period of confusion by providing crisis intervention counseling and identifying those with unusually severe reactions (see Chapter 18).
3. ***Short-term adaptation interventions are aimed at helping children resume their normal lives.*** During this phase of disaster recovery, the goal is to help children make the transition back into normal activity. For example, the school-based social support program provided after Hurricane Hugo (see Chapter 4) greatly assisted children in their reentry to school (Stewart et al., 1992). Classroom activities are often arranged to promote a greater understanding of the circumstances surrounding the disaster and to promote reentry into normal routine. Family therapy and crisis intervention therapy would be provided for those children most adversely affected by the disaster.
4. ***Finally, long-term adaptation services may be needed for children experiencing severe trauma.*** Children experiencing severe reactions to the disaster might need to be seen on a longer-term basis in individual psychological treatment or family therapy.

*It's easy to spot the one child in this group who seems especially vulnerable to the stress of classroom competition. While others have their hands raised or otherwise look alert, her demeanor is withdrawn. Children's inexperience and lack of self-sufficiency make them easily upset by problems that may seem minor to the average adult, and they often have more difficulty in coping with stressful events than they will have when they are older.*

developmental level. Some of the problem behaviors might be considered age-appropriate, and troubling behaviors might simply be ones the child will eventually outgrow.

Over the years, discontent with the classification system for childhood behavior problems has led to considerable rethinking, discussion, and empirical investigation of the issues related to diagnosis. You may recall that in Chapter 1 we discussed various methods of classification. In the classification of childhood disorders, two of these methods—the categorical and the dimensional—have both been prominent. The first approach, a *categorical strategy,* is typically used by clinicians and has evolved from previous diagnostic classification systems. DSM-IV is an example of a categorical strategy. In this strategy, a clinician—or, in the case of DSM-IV, a panel of clinicians—arrives at a descriptive class or category by reviewing the diagnostic literature on the behaviors that appear to define that class of children. For example, the similar behaviors that appear in children who are judged to fit the diagnostic class *attention-deficit hyperactivity disorder* are used as the defining criteria of that class.The second approach—which is rarely used by clinicians but which is favored by many empirical researchers in psychopathology—is a *dimensional strategy.* This approach involves the application of sophisticated statistical methods to provide clear behavior clusters or "dimensions" for the widely observed symptoms manifested by children. A researcher gathers his or her symptomatic information through teachers', parents', or clinicians' observations or through a child's presenting symptoms—that is, the behaviors characteristic of the clinical picture at the time the child is first seen by professional personnel. The researcher then allows the statistical method—for example, factor analysis—to determine the various behavior dimensions evidenced by an individual child. For example, the Child Behavior Checklist (CBCL) is the most widely researched and used dimensional strategy for assessing childhood behavior problems. Achenbach (1985) and colleagues (Achenbach & Edelbrock, 1983; Achenbach & McConaughy, 1985; Achenbach & Weisz, 1975) rated the symptoms of problem children based on two broad dimensions: internalizing and externalizing, which describe the differing tendencies to deal with problems through internal suffering or through external actions against the environment. "Internalizing" symptoms might include depression, social withdrawal, and anxiety, while "externalizing" symptoms might include hyperactivity, aggression, and delinquent behavior.

Both systems are based on observation of a child's behavior, and both result in classifying the child according to the presence or absence of symptoms or problem behaviors. There are marked differences between the systems, however. The categorical approach can require the presence of relatively few symptoms to arrive at a diagnosis. The dimensional approach, on the other hand, usually requires the presence of a number of related symptoms before an individual is considered to have a problem, that is, it usually takes a number of related symptoms on a particular dimension to be considered "extreme." As a result, a categorical system will tend to have many categories defined by few, sometimes quite rare, behaviors, while dimensional approaches typically involve a small number of general classes covering numerous related behaviors.

Broadly, the categorical approach follows the disease model of psychopathology and attempts to classify problem behavior in children into meaningful classes of mental disorders to provide useful prognoses and treatments. The dimensional approach is based on the idea that these behaviors are continuous and are found even among many normal children; it attempts to provide an objective classification scheme for assessing the relative frequency of these behavioral problems in an individual or group. It is possible to see benefits and problems in both these approaches to classification. Because this textbook focuses on the clinical manifestation of disorders, including infrequent symptoms that would be minimized in a dimensional approach, we will, for practical purposes, follow the DSM-IV classification system of childhood and adolescent disorders. Keep in mind, however, that the approach taken here is only one possible way of viewing disorders.

# DISORDERS OF CHILDHOOD

In this section we will discuss several disorders of childhood with a focus on describing the clinical picture of each syndrome, surveying the possible causal factors, and outlining treatment approaches that have proved effective. A broader discussion of treatment methods can be found in Chapters 16 and 17.

The disorders that will be covered are attention-deficit hyperactivity disorder, conduct disorder (including juvenile delinquency), anxiety disorders of childhood, depressive disorders, several other special symptom disorders, and autism. Some of these disorders are less stable than most of the abnormal behavior patterns discussed in earlier chapters and are also perhaps more amenable to treatment. If treatment is not received, childhood developmental problems sometimes merge almost imperceptibly into more serious and chronic disorders as the child passes into adulthood, or they manifest themselves later as different disorders (Gelfand, Jenson, & Drew, 1988).

## Attention-Deficit Hyperactivity Disorder

**Attention-deficit hyperactivity disorder (ADHD),** often referred to as **hyperactivity,** is characterized by difficulties that interfere with effective task-oriented behavior in children, particularly impulsivity, excessive motor activity, and difficulties in sustaining attention. The symptoms of attention-deficit hyperactivity disorder are relatively common among children seen at child guidance centers. In fact, hyperactive children are the most frequent psychological referrals to mental health and pediatric facilities, and it is estimated that between 3 and 5 percent of elementary school–aged children manifest the symptoms (Ross & Pelham, 1981). Attention-deficit hyperactivity disorder is the most frequent disorder among preadolescent boys, with a 6.7 percent prevalence (Anderson et al., 1987). The disorder, which is six to nine times more prevalent among boys than girls (DSM-IV), occurs with the greatest frequency before age eight and tends to become less frequent and with briefer episodes thereafter. As we will see, some residual effects, such as attention difficulties, may persist into adolescence or adulthood.

**The Clinical Picture in Attention-Deficit Hyperactivity Disorder** As the term implies, attention-deficit hyperactive children show excessive or exaggerated muscular activity—for example, aimless or haphazard running or fidgeting. Difficulty in sustaining attention is another central feature of the disorder. Hyperactive children are highly distractible and often fail to follow instructions or respond to demands placed on them. Impulsive behavior and a low frustration tolerance are also characteristic. Perhaps as a result of their behavioral problems, hyperactive children are often lower in intelligence, usually about 7 to 15 IQ points below average. Hyperactive children tend to talk incessantly and to be socially uninhibited and immature. Barkley (1990) pointed out that hyperactive children usually have great difficulties in getting along with their parents because they do not obey rules. Their behavior problems also result in their being viewed negatively by their peers. In general, however, hyperactive children do not appear to be anxious, although their overactivity, restlessness, and distractibility are often interpreted as indications of anxiety. Usually they do poorly in school, commonly showing specific learning disabilities, such as difficulties in reading or in learning other basic school subjects. Hyperactive children also pose behavior problems in the elementary grades. The following case, involving an eight-year-old girl, reveals a typical clinical picture:

> The subject was referred to a community clinic because of overactive, inattentive, and disruptive behavior. She was a problem to her teacher and to other students because of her hyperactivity and her uninhibited behavior. She would impulsively hit other children, knock things off their desks, erase material on the blackboard, and damage books and other school property. She seemed to be in perpetual motion—talking, moving about, and darting from one area of the classroom to another. She demanded an inordinate amount of attention from her parents and her teacher, and she was intensely jealous of other children, including her own brother and sister. Despite her hyperactive behavior, inferior school performance, and other problems, she was considerably above average in intelligence. Nevertheless, she felt "stupid" and had a seriously devaluated self-image. Neurological tests revealed no significant organic brain disorder.

**Causal Factors in Attention-Deficit Hyperactivity Disorder** The lack of clarity in diagnosing hyperactivity results, in part, from the lack of reliable assessment instruments. This unclear differentiation makes it difficult for researchers to evaluate whether biological conditions are involved in causing the disorder.

*Children with ADHD are described as overactive, impulsive, and having a low tolerance for frustration and an inability to delay gratification. Incessant talkers, they tend not to obey rules and often run the risk of a multitude of problems with schoolwork, teachers, and other students.*

The extent to which the problem occurring in ADHD children results from environmental or biological factors is unclear. In a recent comprehensive review of the relationship between externalizing behavior and underachievement, Hinshaw (1992) suggests that low intellectual capacity may be causally linked to both underachievement and externalizing behavior—placing biological factors as likely important precursors in the process. The potential genetic basis for ADHD has not, however, been established. Although by no means overwhelming, there is some support for the idea that ADHD is a familial disorder (Farone, Biederman, & Milberger, 1994). For example, one study reported that siblings of ADHD children were more likely to have had academic tutoring and to have been placed in special classes than controls (Farone et al., 1993). Moreover, brothers of identified ADHD children were more likely to have lower scores on reading tests than controls.

One early viewpoint that received a great deal of public attention suggested that hyperactivity in children may be produced by dietary factors—particularly food coloring (Feingold, 1977). However, the food-additive theory of hyperactivity has generally been discredited (Mattes & Gittelman, 1981; Stare, Whelan, & Sheridan, 1980). Firm conclusions as to the potential biological basis for ADHD must await further research.

The search for psychological causes of hyperactivity has had similarly inconclusive results. Investigators have not clearly established any psychological causes for the disorder, although they have emphasized both temperament and learning factors. Some evidence shows that the home environment is influential in the development of the disorder (Paternite & Loney, 1980). One study suggested that family pathology, particularly parental personality problems, leads to hyperactivity in children. Morrison (1980) found that many parents of hyperactive children had psychological problems; for example, a large number were found to have clinical diagnoses of personality disorder or hysteria. Currently, ADHD is considered to have multiple causes and effects (Barker, 1990; Hinshaw, 1992).

**Treatments and Outcomes** Although the hyperactive syndrome was first described more than 100 years ago, disagreement remains over the most effective methods of treatment, especially regarding the use of drugs to calm a hyperactive child. As with other problem behaviors, variations in treatment procedures may be required to meet the needs of individual children.

Interestingly, research has shown that cerebral stimulants, such as amphetamines, have a quieting effect on hyperactive children—just the opposite of what we would expect from their effects on adults (Green & Warshauer, 1981; Pelham et al., 1992). Such medication decreases hyperactive children's overactivity and distractibility and at the same time increases their attention and ability to concentrate. As a result they are often able to function much better at school (Klorman et al., 1994). Some authorities (Pliszka, 1991) consider stimulants the first drug of choice for treating ADHD. In fact, many hyperactive children who have not been acceptable in regular classes can function and progress in a relatively normal manner when they use such drugs. The medication does not appear to affect their intelligence, but rather seems to help them use their basic capacities more effectively (National Institute of Mental Health, 1971). Although the drugs do not "cure" hyperactivity, they have reduced the behavioral symptoms in about half to two-thirds of the cases in which medication appears warranted. For example, it has been found that medication reduced the problems of inattention but not the impulsivity in hyperactive children (Matier et al., 1992).

While the short-term pharmacologic effect of stimulants on the symptoms of hyperactive children is apparently well established, their long-term effects are not well known. Carlson and Bunner (1993) reported that studies of achievement over long periods of time failed to show that medication has beneficial effects. Some concern has been expressed about the effects of the drugs, particularly when used in heavy dosages over time. Some questions that have been raised concerning the use of these drugs are discussed in HIGHLIGHT 14.2. The use of drug therapy with children will be taken up again in Chapter 16.

Another effective approach to treating hyperactive children involves behavior therapy techniques featuring positive reinforcement and the structuring of learning materials and tasks in a way that minimizes error and maximizes immediate feedback and success (Abramowitz et al., 1992). The use of behavioral treatment methods (see Chapter 17) for hyperactivity has reportedly been quite successful, at least for short-term gains.

The continued use of psychological therapy with medication in a total treatment program has reportedly shown good success. Pelham and colleagues (1980) found that the combination of behavioral intervention and psychostimulant medication was more effective than either treatment alone in modifying the behavior of hyperactive children. Satterfield, Satterfield, and Cantwell (1981) reported that individualized treatment of various types in conjunction with the use of medication resulted in favorable treatment outcomes in a three-year follow-up. In a more recent study, Pelham and colleagues (1993) found that both behavior modification and medication therapy significantly reduced ADHD. Medication, however, appeared to be the more effective element in the treatment.

It should be kept in mind that even though behavioral interventions and medication have reportedly enjoyed short-term successes, there has been insufficient critical evaluation of the long-term effects of either treatment method. One follow-up study of the drug treatment of 75 children over a 10- to 12-year period reported that young adults who had been hyperactive children had less education than control subjects and had a history of more auto accidents and more geographical moves. The authors found, however, that only a minority of the formerly hyperactive subjects continued their antisocial behavior into adulthood or developed severe psychopathology (Weiss et al., 1979).

It is clear from an evaluation of research on the treatment of hyperactivity that, in addition to a general disagreement about the nature of hyperactivity, an equal degree of controversy exists about the most effective treatment approach.

Even without treatment, hyperactive behavior tends to diminish by the time some of the children reach their middle teens. Research has demonstrated, however, that many hyperactive children retain ADHD into early adulthood (Lie, 1992) or go on to have other psychological problems in their late teens and early adulthood. Hechtman, Weiss, and Perlman (1980), for example, found that hyperactive children had significantly more problems than control subjects when they reached young adulthood. Carroll and Rounsaville (1993) found that 34.6 percent of treatment-seeking cocaine abusers in their study met the criteria for ADHD when they were children. In a 16-year follow-up study of ADHD children, about 25 percent never completed high school compared with 2 percent for controls (Mannuzza et al., 1993). Another longitudinal study of ADHD was conducted by Gittleman and colleagues (1985). These investigators evaluated and followed up a group of 101 boys aged 6 through 12 who showed hyperactivity, contrasting their later adjustment, at 16 to 23 years of age, with a control sample of 100 nonhyperactive boys. They found that most boys who had been diagnosed as hyperactive showed diminished symptom patterns in later adolescence and early adulthood. However, the full attention-deficit disorder persisted in 31 percent of the hyperactive boys, while only 3 percent of the control sample showed hyperactive symptoms at follow-up. The authors also found that the hyperactive boys showed a greater likelihood of developing psychiatric problems than the control boys. Their "most striking finding is the degree to which the syndrome consisting of impulsivity, inattention, and hyperactivity persisted" (p. 943), and boys in which the hyperactivity persisted had a greater likelihood of developing conduct disorders. Hyperactive boys who did not receive a clinical diagnosis at follow-up showed no differences from the control boys (Mannuzza et al., 1988).

## Conduct Disorders

The next group of disorders emphasizes a child's or an adolescent's relationship to social norms and

14.2

## Drug Therapy with Children Diagnosed as ADHD

One of the most widely used treatments for attention deficit hyperactivity disorder (ADHD) is psychostimulant medication (Horn et al., 1991). It is estimated that as many as 750,000 children receive medication, such as Ritalin, for overactive behavior every day (Safer & Krager, 1988), even though these medications are only found to be effective in about 75 percent of hyperactive children (DuPaul & Barkley, 1990).

The use of psychostimulant drugs with hyperactive children frequently meets with enthusiasm on the part of parents, school administrators, and clinicians because of their demonstrated effectiveness in controlling disruptive behavior, at least over short periods (Gittelman-Klein, 1987). The reduction in negative behavior, it is assumed, promotes more effective learning and enables the child to adapt better to the school environment and to get along better with peers. However, a number of questions have been raised concerning the increasing use of drugs in the treatment of hyperactive children. The principal questions include:

1. *Who is being selected for treatment?* It is important that an accurate diagnosis be obtained before drug treatment is initiated. However, many question the adequacy of the assessment procedures used in identifying children who actually need medication. For example, a clear-cut distinction is not always made between children who appear to need drug therapy because of hyperactivity and children whose inattention and restlessness may be the result of hunger, crowded classrooms, irrelevant curriculum content, or anxiety and depression stemming from problems at home.

2. *Are drugs sometimes being used simply to control the child's behavior for the convenience of adults, for example, "to keep peace in the classroom"?* Those who raise this question point to the possibility that children who manifest bewilderment, anger, restlessness, or lethargy at school may only be showing a normal reaction to educational procedures that fail to spark their interest or meet their needs. These investigators maintain that to label such children as "sick"—as evidencing hyperactivity or some other behavior disorder—and to treat them through medication is to sidestep the difficult and expensive alternative of providing better educational programs.

3. *Are the effects of medication worth the side effects that accompany its use?* Drugs like Ritalin sometimes have undesirable side effects, such as severe insomnia, decreased appetite, dysphoria, dizziness, and headaches. Recently these drugs have also been suspected as a cause of growth retardation. Appropriate therapeutic dosages are often difficult to assure and higher-than-therapeutic dosages are not uncommon. Excessive dosages have been found to produce brief paranoid psychoses in some individuals (Greenhill, 1992). Even with drugs that seem to produce minimal side effects, the possibility of adverse long-range effects resulting from sustained use during early growth and development is still being assessed.

Drug therapy for children should be used with extreme caution, and only with those children for whom other alternatives simply do not work. It is also important that drug therapy be undertaken only with the informed consent of the parent, as well as that of the child if he or she is old enough, and that the child not be given the sole responsibility for taking the medication—a procedure that can lead to misuse of the drug. At the same time, it is important to recognize that the drugs do help some children. Finally, children who do benefit from drug therapy also need other therapeutic measures for dealing with coexisting problems, such as learning deficiencies and psychological, interpersonal, and family difficulties (DuPaul & Barkley, 1990; Greenhill, 1992).

rules of conduct. In **conduct disorders**, aggressive or antisocial behavior is the focus. With these disorders, it is important to distinguish between persistent antisocial acts, in which the rights of others are violated, and the less serious pranks often carried out by "normal" children and adolescents. We should point out, too, that conduct disorders involve misdeeds that may or may not be against the law; *juvenile delinquency*—to be discussed in the next section—is the legal term used to refer to violations of the law committed by minors.

The behavior to be described in the following sections may appear to be similar to the early stages in the development of personality disorders, discussed in Chapter 9. Indeed, the personality characteristics and causal considerations are much the same. It is difficult, if not impossible, to distinguish among a conduct disorder, a "predelinquent" pattern of behavior, and the early stages in the development of an antisocial personality. Behaviorally, the patterns are alike and may simply represent three ways of describing or accounting for the same behavior. As described in Chapter 9, adult antisocial personalities, as children, showed the aggressive behavior and rule violations that often are labeled conduct disorders, and many came into contact with the authorities as a result of this delinquent behavior. There is substantial evidence that in some children disruptive behavior problems "gradually emerge from childhood onward in an orderly fashion" (Loeber et al., 1992). Fortunately, however, not all children who are described as having conduct disorders or who engage in delinquent behavior grow up to become antisocial personalities or commit themselves to lives of crime. As we will see, although the conduct disorders are quite serious and complex to treat, there are effective ways of working with disordered children.

**The Clinical Picture in Conduct Disorders** The essential symptomatic behavior in the conduct disorders involves a persistent, repetitive violation of rules and a disregard for the rights of others. The following case is typical of children with conduct disorder and illustrates many of the features commonly found:

> Craig, an 8-year-old boy, had already established himself as a social outcast by the time he entered first grade. Previously, he had been expelled from kindergarten two times in two years for being unmanageable. His mother brought him to a mental health center at the insistence of the school when she attempted to enroll him in the first grade. Within the first week of school, Craig's quarrelsome and defiant behavior had tried the special education teacher, who was reputedly "excellent" with problem children like him, to the point where she recommended his suspension from school. His classmates likewise were completely unsympathetic to Craig, whom they viewed as a bully. At even the slightest sign of movement on his part, the other children would tell the teacher that Craig was "being bad again."
>
> At home, Craig was uncontrollable. His mother and six other children lived with his domineering grandmother. Craig's mother was ineffective at disciplining or managing her children. She worked long hours as a domestic maid and "did not feel like hassling with those kids" when she got home. Her present husband, the father of the three youngest children (including Craig), had deserted the family.

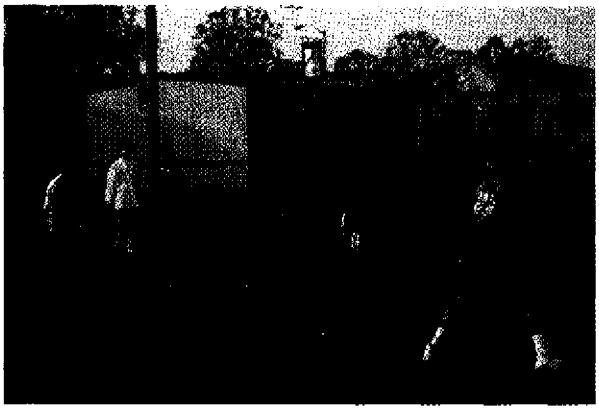
In general, children who are seen as conduct-disordered manifest such characteristics as overt or covert hostility, disobedience, physical and verbal aggressiveness, quarrelsomeness, vengefulness, and destructiveness. Lying, solitary stealing, and temper tantrums are common. Such children tend to be sexually uninhibited and inclined toward sexual aggressiveness. Some may engage in firesetting (Forehand et al., 1991), vandalism, robbery, and even homicidal acts.

**Causal Factors in Conduct Disorders** Our understanding of what factors are associated with the development of conduct problems in childhood has increased tremendously in the past 15 years. An important precursor of the antisocial behavior seen in children with conduct disorder is often what is now called *oppositional defiant disorder*, the essential feature of which "is a recurrent pattern of negativistic, defiant, disobedient and hostile behavior toward authority figures that persists for at least 6 months" (DSM-IV, p. 91). This disorder usually begins by the age of six years, whereas full-blown conduct disorder does not typically begin until the age of nine. Prospective studies have found a developmental sequence from oppositional defiant disorder to conduct disorder, with common risk factors for both conditions (Hinshaw, 1994). That is, virtually all cases of conduct disorder were preceded developmentally by oppositional defiant disorder, although only about 25 percent of children with oppositional defiant disorder go on to develop conduct disorder within a three-year period (Lahey et al., 1992). The risk factors for both include family discord, socioeconomic disadvantage, and antisocial behavior in the parents (Hinshaw, 1994).

Evidence has accumulated that a genetic predisposition leading to low verbal intelligence, mild neuropsychological problems, and difficult temperament sets the stage for this early-onset conduct disorder through a set of self-perpetuating mechanisms (Caspi, Elder, & Herbener, 1990; Hinshaw, 1994; Moffitt & Lynam, 1994). The child's difficult temperament may lead to an insecure attachment because parents find it hard to engage in the good parenting that would lead to a secure attachment. In addition, low verbal intelligence and/or mild neuropsychological deficits (some of which may involve deficiencies in self-control functions such as sustaining attention, planning, self-monitoring, inhibiting unsuccessful or impulsive behaviors) which have been documented in many of these children, may help set the stage for a lifelong course of difficulties. In attempting to explain why the relatively mild neuropsychological deficits typically seen can have such pervasive effects, Moffitt and Lynam hypothesize:

> Perhaps the effects of early neuropsychological vulnerabilities are amplified over time as children interact with their environments, to later culminate in conduct disorder. For example, a preschooler who has difficulty understanding language may resist his mother's efforts to read to him, which delays his school readiness. When he enters school, the modal curriculum may not allow for teaching that is tailored to his readiness level, especially if the school is crowded and the resources are poor. After a few years of school failure, he will be chronologically older than his class mates, and thus be socially rejected. He may be tracked into a remedial class, containing pupils who have behavioral disorders as well as learning disabilities. Daily association with conduct-disordered peers brings familiarity with delinquent behaviors, and he adopts delinquent ways to gain acceptance by peers. In this way, a relatively mild neuropsychological deficit might initiate an invidious sequence of interactions between individual characteristics and social contexts, culminating in an antisocial personality style. (1994, pp. 243–44)

Children who develop conduct disorder early are much more likely to develop psychopathy or antisocial personality disorder as adults than are adolescents who develop conduct disorder suddenly in adolescence (Hinshaw, 1994; Moffitt, 1993b). Thus, it is the pervasiveness of the problems first associated with oppositional defiant disorder, and then with early-onset conduct disorder, which is the pattern associated with an adult diagnosis of psychopathy or antisocial personality. Although only about 25–40 percent of cases of early-onset conduct disorder go on to develop adult antisocial personality disorder, over 80 percent of boys with early-onset conduct disorder do continue to have multiple problems of social dysfunction (in friendships, intimate relationships, and vocational activities) even if they do not meet full criteria for antisocial personality disorder (Hinshaw, 1994; Zoccolillo et al., 1992). By contrast, most adolescents who develop conduct disorder in adolescence do not go on to become adult psychopaths or antisocial personalities but instead have problems limited to the adolescent years. These adolescent-onset cases also do not share the same set of risk factors that the child-onset cases have, including low verbal intelligence, neuropsychological deficits, and impulsive and attentional problems (Hinshaw, 1994; Moffitt & Lynam, 1994).



*Hostility and aggressive behavior have been found to play a role in the development of conduct disorder. Children who develop this disorder early in childhood are at special risk for problems later in life.*

In addition to these genetic or constitutional liabilities that may predispose to conduct disorder and adult psychopathy and antisocial personality, a host of environmental factors also may contribute. For example, Coie and Lenox (1994) have summarized evidence showing that children who are aggressive and socially unskilled are often rejected by their peers and that such rejection can lead to "a spiraling sequence of social interactions with peers that exacerbates the tendency toward antisocial behavior (Dodge, 1980)" (Coie & Lenox, 1994). They have also shown that it is the socially rejected subgroup of aggressive children who are at the highest risk for adolescent delinquency and probably for adult antisocial personality. In addition, parents and teachers may react with strong negative affect, such as anger, to aggressive children (Capaldi & Patterson, 1994), and parents and teachers may in turn also reject these aggressive children. The combination of rejection by parents, peers, and teachers leads these children to become isolated and alienated. Not surprisingly, they often turn to deviant peer groups for companionship (Coie & Lenox, 1994), at which point a good deal of imitation of the antisocial behavior of their deviant peer models may occur.

Investigators generally seem to agree that the family setting of a conduct-disordered child is typically characterized by ineffective parenting, rejection, harsh and inconsistent discipline, and often parental neglect (Frick et al., 1992; Patterson, DeBarsyshe, & Ramsey, 1989; Patterson, Reid, & Dishion, 1992). Frequently, the parents have an unstable marital relationship (Osborn, 1992), are emotionally disturbed or sociopathic, and do not provide the child with consistent guidance, acceptance, or affection. Family discord, such as the conflict and disharmony accompanying divorce, is instrumental in the development of conduct disorders (Chess & Thomas, 1984; Robins, 1991). In a disproportionate number of cases, the child may have a single parent, a stepparent, or a series of stepparents. Regardless of whether the family is intact, a child in a conflict-charged home feels overtly rejected. Rutter and Quinton (1984b), for example, concluded that family discord and hostility were "the chief mediating variables" in the association between disturbed parents and disturbed children, particularly with regard to the development of conduct disorders in children and adolescents. These parental factors are conceptualized as contributing to poor and ineffective parenting skills—especially ineffective discipline and supervision. "These children are trained by the family directly in antisocial behavior by coercive interchanges and indirectly by lack of monitoring and consistent discipline" (Capaldi & Patterson, 1994, p. 169). This in turn all too often leads to association with deviant peers and the opportunity for further learning of antisocial behavior.

In addition to the familial factors, a number of other psychosocial and sociocultural contextual variables probably contribute to the probability that a child will develop conduct disorder, and later adult psychopathy or antisocial personality disorder. As summarized by Capaldi and Patterson (1994), these include low socioeconomic status, poor neighborhoods, parental stress, and depression.

**Treatments and Outcomes** Therapy for a conduct-disordered child is likely to be ineffective unless some means can be found for modifying the child's environment. One interesting and often effective treatment strategy with conduct disorder in children is the *cohesive family model* (Patterson et al., 1992; Webster-Stratton, 1991). In this approach, parents of conduct-disordered children are viewed as lacking in parenting skills and fail to socialize the children by behaving in inconsistent ways, thereby reinforcing inappropriate behavior. Patterson and his colleagues have developed a "coercive hypothesis" which holds that children learn to escape or avoid parental criticism by escalating their negative behavior. This tactic in turn increases their parents' aversive interactions and criticism. The child observes the increased anger in his or her parents and models this aggressive pattern. The parental attention to the child's negative behaviors actually serves to reinforce the negative, aggressive behavior instead of suppressing it. Viewing the genesis of conduct problems as emerging from the parent-child interaction places the treatment focus on the interaction between the child and the parents (Patterson et al., 1992).

Obtaining treatment cooperation from parents who are themselves in conflict with each other is often a very difficult process. Often an overburdened parent who is separated or divorced and working simply does not have the time or inclination to learn and practice a more adequate parental role. In some cases, the circumstances may call for a child to be removed from the home and placed in a foster home or institution, with the expectation of a later return to the home if intervening therapy with the parents appears to justify it. Unfortunately, children who are removed to new environments often interpret this removal as further rejection—not only by their parents but by society as well. Unless the changed environment offers a warm, kindly, and accepting—yet consistent and firm—setting, such children are likely to make little progress. Even then, treatment may have only a temporary effect. Faretra (1981) followed up 66 aggressive and disturbed adolescents who had been admitted to an inpatient unit. She found that antisocial and criminal behavior persisted into adulthood with a lessening of psychiatric involvement. Many conduct-disordered children go on to have personality disorders as adults (Rutter, 1988; Zeitlin, 1986).

Aggressiveness at an early age has been found to be related to adult personality disorder (Zoccolillo et al., 1992) or criminal behavior. Stattin and Magnusson (1989) conducted a study of 1027 boys and girls between late childhood and early adolescence using teacher ratings made at ages 10 and 13. An evaluation of the recorded behavior problems of the boys through age 26 found that high ratings of childhood aggressiveness were characteristic of subjects who later committed violent crimes and damage to public property. The relationship between early aggressiveness and later crime was not found for girls.

By and large, our society tends to take a punitive, rather than rehabilitative, attitude toward an antisocial, aggressive youth. Thus, the emphasis is on punishment and on "teaching the child a lesson." Such "treatment," however, appears to intensify rather than correct the behavior. Where treatment is unsuccessful, the end product is likely to be an antisocial personality with aggressive behavior.

The advent of behavior therapy techniques has, however, made the outlook brighter for children who manifest conduct disorders (Kazdin, 1988). Teaching control techniques to the parents of such children is particularly important, so that they function as therapists in reinforcing desirable behavior and modifying the environmental conditions that have been reinforcing maladaptive behavior. The changes brought about when they consistently accept and reward their child's positive behavior and stop focusing attention on the negative behavior may finally change their perception of and feelings toward the child, leading to the basic acceptance that the child has so badly needed.

Though effective techniques for behavioral management can be taught to parents, often they have difficulty carrying out treatment plans. If this is the case, other techniques, such as family therapy or parental counseling, can be employed to ensure that the parent or person responsible for the child's discipline is sufficiently assertive to follow through on the program.

## Delinquent Behavior

In this section we will examine one of the most troublesome and extensive problems in childhood and adolescence: delinquent behavior. This behavior includes such acts as destruction of property, violence against other people, and various behaviors contrary to the needs and rights of others and in violation of society's laws (Henggeler, 1989). As noted earlier, the term **juvenile delinquency** is a legal one; it refers to illegal acts committed by individuals under the age of 16, 17, or 18 (depending on state law). Children under eight who commit such acts are not considered delinquents, because it is assumed that they are too immature to understand the significance and consequences of their actions. Delinquency is generally regarded as calling for some punishment or corrective action.

**The Incidence and Severity of Delinquent Acts** The actual incidence of juvenile delinquency is difficult to determine because many delinquent acts are not reported. Of the 2 million young people who go through the juvenile courts each year in the United States, about half are there for actions, such as running away, that are not considered crimes for adults. These actions are referred to as status offenses (see HIGHLIGHT 14.3). In 1988, arrests of people under 18 years of age accounted for 28 percent of all crime (Uniform Crime Reports, 1992). Juveniles accounted for over one out of every three arrests for robbery, one out of three arrests for crimes against property, one out of six arrests for rape, and one out of eleven arrests for murder. Although most of the juvenile crime was committed by males, the rate has also risen for females. About 1 teenager out of every 15 in the nation was arrested. Well over half of the juveniles who are arrested each year have prior police records (Uniform Crime Reports, 1992). Female delinquents are commonly apprehended for drug use, sexual offenses, running away from home, and "incorrigibility," but crimes against property, such as stealing, have markedly increased among this group. Male delinquents are commonly arrested for drug usage and crimes against property; to a lesser extent, they are arrested for armed robbery, aggravated assault, and other crimes against people.

Fear of violent juvenile crime has created in many people the idea that juvenile criminals as a group are uncontrollable and antisocial personalities. Indeed, a high percentage of violent crimes (17.5 percent) are committed by persons under 18 years of age or younger (Uniform Crime Reports, 1992).

Both the incidence and the severity of delinquent behavior are disproportionately high for lower-class adolescents (Zimring, 1979). It may also be noted that the delinquency rate for socially disadvantaged youths appears about equal for whites and nonwhites (Uniform Crime Reports, 1992). Although much juvenile crime is committed by lower-class youth, some problems have been noted in all social strata (Elliott, Dunford, & Huizinga, 1987).

**Causal Factors in Delinquency** In an interesting theoretical analysis of delinquency, Moffitt (1993) points out that most contemporary views of delinquency have failed to recognize the heterogeneity of delinquency and calls for a more refined view of its origins. She notes that a small group of adolescents show continuous delinquency over time whereas most delinquent adolescents engage in delinquent acts and discontinue this behavior soon afterward. Moffitt suggests that the small group of "continuous" delinquents actually evolve from oppositional defiant behavior to conduct disorder then to adult antisocial personality while most people who engage in delinquent acts as adolescents do not follow this trend. The individuals who show adolescence-limited delinquency are thought to do so as a result of social mimicry—they mimic their more antisocial peers but discontinue this behavior when they ultimately respond to changing contingencies. That is, they lose their motivation for delinquency as they mature and respond to other contingencies in their environment.

Various conditions, singly and in combination, may be involved in the development of delinquent behavior. Several key variables seem to play a part in

14.3

## Problems That Lead Children to Run Away

Of serious concern in the United States is the problem of youngsters who run away from home—an estimated 1 million or more each year. Although the average age is about 15, an increasing number are in the 11- to 14-year-old age bracket. Many of these runaways are from the suburbs, and at least half are girls. The following case illustrates this problem:

> Joan, an attractive girl who looked older than her 12 years, came to the attention of juvenile authorities when her parents reported her as a runaway. Twice before she had run away from home, but no report had been filed. In the first instance, she had gone to the home of a girlfriend and returned two days later; in the second, she had hitchhiked to another city with an older boy and returned home about a week later. Investigation revealed that the girl was having difficulty in school and was living in a family situation torn by bickering and dissension. In explaining why she ran away from home, she stated simply that she "just couldn't take it anymore—all that quarreling and criticism, and no one really cared anyway."

Why do children and adolescents run away? English (1973) concluded that reasons for running away from home tend to fall into three categories: (a) getting out of a destructive family situation, as in the case of a girl who runs away to avoid sexual advances by her father or stepfather; (b) running away in an effort to better the family situation; and (c) having a secret, unsharable problem, such as, for girls, being pregnant.

In a study of runaway girls, Homer (1974) distinguished between "run from's," who had usually fought with their parents and run away because they were unable to resolve the situation or their anger, and "run to's," who were seeking something outside the home. The "run to's" were typically seeking pleasure—sex, drugs, liquor, escape from school, or a peer group with similar interests. Usually they stayed with friends or at other "peer-established" facilities. The "run from's" usually ran away from home only once, while the "run to's" were more likely to be repetitive runaways.

An increasing number of children are "run from's" who are trying to get away from intolerable home situations. Several recent studies have pointed to the possibility that children who run away have been physically or sexually abused (Famularo, et al., 1990; Feitel et al., 1992; Powers, Eckenrode, & Jaklitsch, 1990). In some instances, for economic or other reasons, they are actually encouraged to leave—and their parents do not want them back. Most do not feel that they can return to their parents but instead want a foster home where they will be treated well and respected.

The majority of runaways are not reported. Of those who are, about 90 percent or more are located by law enforcement officers and, when feasible, returned home. Beginning in 1974, a toll-free hotline was established that informs runaways where the nearest temporary shelter is located and enables them to send messages to their parents if they wish. Treatment for runaways is similar to that for individuals who manifest other emotional problems during childhood and adolescence. Often family therapy is an essential part of the treatment program. In some instances—as in those involving parental abuse, unconcern, or lack of cooperation—juvenile authorities may place a child in a foster home. Parents, however, are by no means always the primary reason for their child's running away, and a "what-have-we-done-wrong" attitude may lead to unnecessary feelings of guilt. One of the toll-free numbers is 1-800-621-4000. This hotline does not operate in either Alaska or Hawaii.

the genesis of delinquency: personal pathology, pathogenic family patterns, undesirable peer relationships, general sociocultural factors, and special stress.

*Personal Pathology.* A number of investigators have attempted to understand delinquents in terms of pervasive patterns and sources of personal pathology:

1. *Genetic determinants.* Although the research on genetic determinants of antisocial behavior is far from conclusive, some evidence indicates possible hereditary contributions to criminality. Schulsinger (1980) identified 57 sociopathic adoptees from psychiatric and police files in Denmark and matched them with 57 nonsociopathic control adoptees on the basis of age, sex, social class, geographic region, and age at adoption. He found that natural parents

of the adopted sociopaths, particularly fathers, were more likely to have sociopathic characteristics than the natural parents of the controls. Because these natural parents had little contact with their offspring, thus reducing the possibility of environmental influence, the results are interpreted as reflecting the possibility of some genetic transmission of a predisposition to antisocial behavior.

2. *Brain damage and learning disability.* In a distinct minority of delinquency cases—an estimated 1 percent or less—brain pathology results in lowered inhibitory controls and a tendency toward episodes of violent behavior. Such adolescents are often hyperactive, impulsive, emotionally unstable, and unable to inhibit themselves when strongly stimulated. Fortunately, their inner controls appear to improve during later adolescence and young adulthood. The actual role intellectual factors, particularly learning disabilities, play in causing juvenile delinquency is still being debated. In a recent review of the evidence, Lombardo and Lombardo (1991) concluded that there is no empirical evidence linking learning disabilities with delinquency. However, Lynam, Moffitt, and Stouthamer-Loeber (1993) found a clear relationship between low intelligence and delinquency.

3. *Psychological disorders.* A small percentage of delinquent acts appear to be directly associated with behavior disorders, such as hyperactivity (Loeber et al., 1992). Delinquent acts associated with psychotic behavior often involve a pattern of prolonged emotional hurt and turmoil, culminating, after long frustration, in an outburst of violent behavior (Bandura, 1973). In the case of psychologically disturbed delinquents, the delinquent act is a by-product of severe personality maladjustment rather than a reflection of antisocial attitudes.

4. *Antisocial traits.* Many habitual delinquents appear to share the traits typical of antisocial personalities—they are impulsive, defiant, resentful, devoid of feelings of remorse or guilt, incapable of establishing and maintaining close interpersonal ties, and seemingly unable to profit from experience. Because they lack needed reality and ethical controls, they often engage in seemingly senseless acts that are not planned but occur on the spur of the moment. They may steal a small sum of money they do not need, or they may steal a car, drive it a few blocks, and abandon it. In some instances, they engage in impulsive acts of violence that are not committed for personal gain but rather reflect underlying resentment and hostility toward the world. In essence, these individuals are "unsocialized."

5. *Drug abuse.* Many delinquent acts—particularly theft, prostitution, and assault—are directly associated with alcohol or drug use. Most adolescents who abuse hard drugs, such as heroin, are forced to steal to maintain their habit, which can be very expensive. In the case of female addicts, theft may be combined with or replaced by prostitution as a means of obtaining money.

*Teen prostitution is often directly associated with alcohol or drug use. For female addicts, prostitution is a means of obtaining money.*

*Pathogenic Family Patterns.* In evaluating the role of pathogenic family patterns in delinquency, it should be emphasized that a given pattern is only one of many interacting factors. Of the various patterns that have been emphasized in the research on juvenile delinquency, the following appear to be the most important:

1. *Parental absence or family conflict.* Parents may be missing because of desertion, separation, death, or imprisonment. Several investigators have pointed to the high incidence of multiple or missing parental figures in the backgrounds of delinquent youths (Lefkowitz et al., 1977). In general, delinquency appears to be much more common among youths coming from homes in which parents have separated or divorced than from homes in which a parent has died, suggesting that parental conflict may be a key element in causing delinquency. As we have seen, the effects of parental absence vary. Parental separation or divorce may be less serious for children than parental conflict and dissension. It is parental disharmony and conflict in lieu of a stable home life that appears to be an important causal variable.

2. *Parental rejection and faulty discipline.* In many cases, one or both parents reject a child. When the father is the rejecting parent, it is difficult for a boy to identify with him and use him as a model for his own development. In an early study of 26 aggressively delinquent boys, Bandura and Walters

(1963) delineated a pattern in which rejection by the father was combined with inconsistent handling of the boy by both parents. To complicate the pathogenic picture, the father typically used physically punitive methods of discipline, thus modeling aggressive behavior and augmenting the hostility that the boy already felt toward him. The end result of such a pattern was a hostile, defiant, inadequately socialized youth who lacked normal inner controls and tended to act out his aggressive impulses in antisocial behavior.

The detrimental effects of parental rejection and inconsistent discipline are by no means attributable only to fathers. Researchers have found that such behavior by either parent is associated with aggression, lying, stealing, running away from home, and a wide range of other difficulties (Lefkowitz et al., 1977). Often, too, inconsistent discipline may involve more complex family interactions, as when a mother imposes severe restrictions on a youth's behavior and then leaves "policing" to a timid or uncaring father who fails to follow through. In general, parental supervision has been found to be inversely related to delinquency—higher rates of delinquency are found in families that provide less supervision for their children (Morton & Ewald, 1987).

3. *Antisocial parental models.* Several investigators have found a high incidence of antisocial traits in the parents of delinquents—particularly but not exclusively in the father (Bandura, 1973). These traits included alcoholism, brutality, antisocial attitudes, failure to provide, frequent unnecessary absences from home, and other characteristics that made the father an inadequate and unacceptable model. Elkind (1967), for example, cited the case of a

> father who encouraged his 17-year-old son to drink, frequent prostitutes, and generally "raise hell." This particular father was awakened late one night by the police who had caught his son in a raid on a so-called "massage" parlor. The father's reaction was, "Why aren't you guys out catching crooks?" This same father would boast to his coworkers that his son was "all boy" and "a chip off the old block." (p. 313)

Psychopathic fathers—and mothers—may contribute in various ways to the delinquent behavior of girls as well. Covert encouragement of sexual promiscuity is fairly common, and in some instances there is actual incest with the daughter. In a study of 30 delinquent girls, Scharfman and Clark (1967) found evidence of serious psychopathology in one or both parents of 22 of the girls, including three cases of incest and many other types of early sexual experience. These investigators also reported a high incidence of parental absence (only 11 of the 30 girls lived with both parents) and harsh, irrational, and inconsistent discipline:

*Youth gangs offer acceptance and affection that are often absent in the adolescent's home and school environment.*

> Any form of consistent discipline or rational setting of limits was unknown to the girls in their homes. Rather, there was an almost regular pattern of indifference to the activities or whereabouts of these girls, often with the mother overtly or indirectly suggesting delinquent behavior by her own actions. This would alternate with unpredictable, irrational, and violent punishment. (p. 443)

4. *Limited parental relationships outside the family.* Some research suggests that the parents' interpersonal relationships outside the family may contribute to their children's delinquency (Griest & Wells, 1983). Wahler (1980) found that the children's acting-out behavior was inversely related to the amount of friendly contacts that parents had outside the home. Wahler, Hughey, and Gordon (1981) reported that mothers who are isolated or who have negative community interactions are less likely to "track" or control their children's behavior in the community than parents who have friendly relationships outside the family.

*Undesirable Peer Relationships.* Delinquency tends to be a shared experience. In their study of delinquents in the Flint, Michigan, area, Haney and Gold (1973) found that about two-thirds of delinquent acts were committed in association with one or two other people, and most of the remainder involved three or four other people. Usually the offender and the companion or companions were of the same sex. Interestingly, girls were more likely than boys to have a constant friend or companion in delinquency. The role of gang membership in delinquency is discussed in the next section.

*General Sociocultural Factors.* Broad social conditions may also tend to produce or support delinquency. Interrelated factors that appear to be of key importance include alienation and rebellion, social rejection, and the psychological support afforded by membership in a delinquent gang.

Feelings of alienation and rebellion are common to many teenagers from all socioeconomic levels. Alienated teenagers may outwardly submit passively to their elders' demands, or they may openly disobey parental and other adult authority and create no end of problems for themselves and their families. In either event, alienation from family and from the broader society exposes them to becoming captives of their peers, to whom they may turn for guidance and approval.

Our society has become increasingly aware of young people who lack the motivation or ability to do well in school and who drop out as soon as they can (Schwartz & Johnson, 1985). With increasing automation and the demand for occupational skills, there are few jobs for which they can qualify. There are also many students who graduate from high school but whose training does not qualify them for available jobs. Whether these young people come from upper-, middle-, or lower-income homes, and whether they drop out or continue through high school, they have one crucial problem in common—they discover that they are not needed in our society. They are victims of social progress—"social rejects." While some are able to obtain training in specific job areas, others appear unable to find or hold jobs, and still others drift aimlessly from one unsatisfactory job to another.

Among adolescents who join gangs, we are dealing not so much with personal psychopathology as with organized group pathology involving rebellion against the norms of society. As Jenkins (1969) has expressed it:

> The socialized delinquent represents not a failure of socialization but a limitation of loyalty to a more or less predatory peer group. The basic capacity for social relations has been achieved. What is lacking is an effective integration with the larger society as a contributing member. (p. 73)

Although the problem of delinquent gangs is most prevalent in lower-socioeconomic areas, it is by no means restricted to them. Further, delinquent gangs are not a male province—in recent years, females have also formed gangs. Nor does the problem of juvenile delinquent gangs occur only in particular racial, ethnic, or social groups. It is pervasive, most particularly in inner-city areas. Though there are many reasons for joining gangs, most members appear to feel inadequate in and rejected by the larger society. Gang membership gives members a sense of belonging and a means of gaining some measure of status and approval. It may also represent a means of committing robberies and other illegal acts for financial gain—acts that an individual could not successfully perform alone (Feldman & Weisfeld, 1973).

We should emphasize that the most delinquents do not belong to delinquent gangs, though gang membership may be increasing because young people appear to be joining groups for protection. Not all delinquent gangs are highly organized, cohesive groups. Recently, however, there seems to be an increase in both the organization and cohesiveness of delinquent gangs and in the violence of their activities.

**Dealing with Delinquency** If they have adequate facilities and personnel, juvenile institutions and training schools can be of great help to youths who need to be removed from aversive environments. These institutions can give youths a chance to learn about themselves and their world, to further their education and develop needed skills, and to find purpose and meaning in their lives. In such settings, young people may have the opportunity to receive psychological counseling and group therapy. In these situations it is of key importance that peer group pressures be channeled in the direction of resocialization, rather than toward repetitive delinquent behavior. Behavior therapy techniques based on the assumption that delinquent behavior is learned, maintained, and changed according to the same principles as other learned behavior have shown promise in the rehabilitation of juvenile offenders who require institutionalization. Counseling with parents and related environmental changes are generally of vital importance in a total rehabilitation program.

Probation is widely used with juvenile offenders and may be granted either in lieu of or after a period of institutionalization. Many delinquents can be guided into constructive behavior without being removed from their family or community.

The recidivism rate for delinquents—the most commonly used measure for assessing rehabilitation programs—depends heavily on the type of offenders being dealt with and on the particular facility or procedures used. The overall recidivism rate for delinquents sent to training schools has been estimated to be high (Uniform Crime Reports, 1989). Because many crimes are committed by juveniles who have been recently released from custody or who were not incarcerated after being arrested, a number of state officials have become advocates of stiffer penalties for some types of juvenile crime. Individuals who commit crimes of violence or armed assault, or who have a long history of arrests, are often being given harsher penalties than they once would have been (Fersch, 1980).

## Anxiety Disorders of Childhood and Adolescence

In modern society, no one is totally insulated from anxiety-producing events or situations. Most children are vulnerable to fears and uncertainties as a part of growing up, and most children encounter many normal developmental steps and environmental demands that challenge their adaptation skills. Anxiety disorders are apparently quite common in the general population. Kashani and Orvaschel (1988) reported that 8.7 percent of their community-based school sample clearly met diagnostic criteria for an anxiety diagnosis based on a diagnostic interview.

Children with anxiety disorders are more extreme in their behavior than those experiencing "normal" anxiety. These children appear to share many of the following characteristics: oversensitivity, unrealistic fears, shyness and timidity, pervasive feelings of inadequacy, sleep disturbances, and fear of school. Children diagnosed as suffering from an anxiety disorder typically attempt to cope with their fears by becoming overly dependent on others for support and help.

In DSM-IV, anxiety disorders of childhood and adolescence are covered in two subclassifications: separation anxiety disorder and overanxious disorder. Both syndromes are more common among boys than among girls. We will briefly describe the clinical picture in each of these syndromes, then deal with causal factors and treatment considerations.

**Separation Anxiety Disorder** Separation anxiety disorder is the most common of the childhood anxiety disorders (Bernstein & Borchardt, 1991), reportedly occurring with a prevalence of 2.4 percent of children in a population health study (Bowen, Offord, & Boyle, 1990). Children with **separation anxiety disorder** are characterized by unrealistic fears, oversensitivity, self-consciousness, nightmares, and chronic anxiety. They lack self-confidence, are apprehensive in new situations, and tend to be immature for their age. Such children are described by their parents as shy, sensitive, nervous, submissive, easily discouraged, worried, and frequently moved to tears. Typically, they are overly dependent, particularly on their parents. The essential feature in the clinical picture of this disorder is excessive anxiety about separation from major attachment figures, such as mother, and from familiar home surroundings. In many cases a clear psychosocial stressor can be identified, such as the death of a relative or a pet. The following case illustrates the clinical picture in this disorder:

> Johnny was a highly sensitive six-year-old boy who suffered from numerous fears, nightmares, and chronic anxiety. He was terrified of being separated from his mother, even for a brief period. When his mother tried to enroll him in kindergarten, he became so upset when she left the room that the principal arranged for her to remain in the classroom. After two weeks, however, this arrangement had to be discontinued, and Johnny had to be withdrawn from kindergarten because his mother could not leave him even for a few minutes. Later, when his mother attempted to enroll him in the first grade, Johnny manifested the same intense anxiety and unwillingness to be separated from her. At the suggestion of the school counselor, Johnny's mother brought him to a community clinic for assistance with the problem. The therapist who initially saw Johnny and his mother was wearing a white clinic jacket, which led to a severe panic reaction on Johnny's part. His mother had to hold him to keep him from running away, and he did not settle down until the therapist removed his jacket. Johnny's mother explained that "he is terrified of doctors, and it is almost impossible to get him to a physician even when he is sick."

When children with separation anxiety disorder are actually separated from their attachment figures, they typically become preoccupied with morbid fears, such as the worry that their parents are going to become ill or die. They cling helplessly to adults, have difficulty sleeping, and become intensely demanding.

**Overanxious Disorder** Children with **overanxious disorder** are characterized by excessive worry and persistent fear; however, their fears are usually not specific and are not due to a recent stressful event. Such a child appears generally anxious and may worry a great deal about future events. He or she is preoccupied with trivial problems. His or her anxiety may also be expressed in somatic ways—stomach distress, shortness of breath, dizziness, headaches, and the like. Sleeping problems, especially difficulty in falling asleep, are common. Many children showing overanxious disorder appear to have personality characteristics such as perfectionistic ideas and obsessional self-doubt. One study (Bowen et al., 1990) found overanxious disorder in 3.6 percent of a sample of children in a large epidemiological study in Canada. The disorder is illustrated in the following case:

Cindy, an overweight eleven-year-old girl, was taken to the emergency room following an "attack" of dizziness, faintness, and shortness of breath. She believed she was having a heart attack because of the discomfort she was experiencing in her chest. Cindy had a long history of health problems and concerns and was a frequent visitor to doctors. She had missed, on the average, three days of school a week since school had begun four months before.

Cindy was viewed by her mother as a "very good girl" but "sickly." Cindy was good about helping around the house and with her two younger sisters. She seemed conscientious and concerned about doing things right but seemed to lack self-confidence. She always checked out things with her mother, sometimes several times. She was particularly concerned about safety and would, for example, ask her mother frequently if the kitchen stove was turned off correctly.

Cindy would become extremely fearful at times, often for no external reason. For example, on one clear summer day a few months before, she had become panicked over the possibility that a tornado might strike and had insisted that her family take shelter for several hours in the basement.

**Causal Factors in Anxiety Disorders** A number of causal factors have been emphasized in explanations of the childhood anxiety disorders. The more important appear to be the following:

1. An unusual constitutional sensitivity, an easy conditionability by aversive stimuli, and a buildup and generalization of "surplus fear reactions."

2. The undermining of feelings of adequacy and security by early illnesses, accidents, or losses that involved pain and discomfort. The traumatic effect of such experiences is often due partly to such children finding themselves in unfamiliar situations, as during hospitalization. The traumatic nature of certain life changes, such as moving away from friends and into a new situation, can have an intensely negative effect on a child's adjustment. Kashani and colleagues (1981a) found that the most common recent life event for children receiving psychiatric care was moving to a new school district.

3. The "modeling" effect of an overanxious and protective parent who sensitizes a child to the dangers and threats of the outside world. Often the parent's overprotectiveness communicates a lack of confidence in the child's ability to cope, thus reinforcing the child's feelings of inadequacy.

4. The failure of an indifferent or detached parent to provide adequate guidance for a child's development. Although the child is not necessarily rejected, neither is he or she adequately supported in mastering essential competencies and in gaining a positive self-concept. Repeated experiences of failure, stemming from poor learning skills, may lead to subsequent patterns of anxiety or withdrawal in the face of "threatening" situations. Other children may perform adequately but are overcritical of themselves and feel intensely anxious and devaluated when they perceive themselves as failing to do well enough to earn their parents' love and respect.

5. Finally, the role that social-environmental factors might play in the development of anxiety-based disorders, though important, is not clearly understood. One recent study (Last & Perrin, 1993) reported that there were clear differences between African American and white children with respect to types of anxiety disorders. White children were more likely to present with school refusal than African American children who showed more PTSD symptoms. This difference might result from differing patterns of referral in African American or white families or might reflect differing environmental stressors placed on the children. Further research is needed to determine the implications of these findings.

The various causal factors we have been discussing in relation to childhood anxiety disorders can obviously occur in differing degrees and combinations. All of them, however, are consistent with the view that these disorders essentially result from maladaptive learning.

**Treatments and Outcomes** The anxiety disorders of childhood may continue into adolescence and young adulthood—first leading to maladaptive avoidance behavior and later to increasingly idiosyncratic thinking and behavior. Typically, however, this is not the case. As affected children grow and have wider interactions in school and in peer-group activities, they often benefit from such corrective experiences as making friends and succeeding at given tasks. Teachers who are aware of the needs of both overanxious and shy, withdrawn children are often able to ensure successful experiences for them.

Psychopharmacological treatment of anxiety disorders in children and adolescents is becoming more common today (Kutcher et al., 1992) although the effectiveness of drugs such as imipramine with problems such as overanxious disorder have questionable efficacy. Moreover, one factor contributing to caution in using medications in these disorders is the diagnostic uncertainty involved. Anxiety is often found to coexist with other conditions, particularly depression (Gittelman, 1988) and ADHD (Andreason et al., 1987). Often there is not the diagnostic clarity required for cautious use of antianxiety medication.

Behavior therapy procedures, sometimes used in school settings, often help anxious children. Such procedures include assertiveness training, help with mastering essential competencies, and desensitization. Recently, one researcher reported the successful use of cognitive-behavioral treatment with 9- to 13-year-old children with anxiety disorders (Kendall, 1994). With children, behavioral treatment approaches such as desensitization must be explicitly tailored to a particular problem, and in vivo methods (using graded real-life situations) may be more effective than the use of imagined situations. Although behavior therapy has been demonstrated to be effective with anxious children, some investigators have questioned whether it is superior to other approaches (Barrios & Hartman, 1988). For a look at two other therapies that are often successful with children experiencing anxiety, see HIGHLIGHT 14.4.

## Childhood Depression

Clinicians working with children in mental health settings have long noted a pattern of symptoms that seemed indicative of depression. Spitz (1946) first described the problem, which he called ***anaclitic depression,*** as a behavior pattern, similar to adult depression, that occurred in children experiencing prolonged separation from their mothers. This specific childhood depression syndrome included slowed development and such symptomatic behavior as weepiness, sadness, immobility, and apathy. Recent research has confirmed that depression in children and adolescents occurs with alarming frequency. Estimates of the frequency of depressive symptoms in children have ranged from 13 percent (Kashani et al., 1982) to 23 percent (Kashani, Venzke, & Millar, 1981). Lefkowitz and Tesiny (1985), in a large-scale study of "normal" children in an elementary school system, found the overall prevalence rate of depressive symptoms to be 5.2 percent. A marked rise in depressive symptoms occurs during teenage years (Fleming, Offord, & Boyle, 1989; Peterson et al., 1993). Lewinsohn and colleagues (1993) surveyed 1710 high school students and reported that point prevalence (the rate at the time of the assessment) was 2.9 percent and that lifetime prevalence was 20.4 percent. Depression occurs at about twice the rate for adolescent girls as for adolescent boys. Lewinsohn and colleagues (1993) also reported that 7.1 percent of the adolescents surveyed reported having attempted suicide in the past and, in a more recent epidemiological study, Lewinsohn, Rohde, and Seeley (1994) pointed out that 1.7 percent of adolescents between 14 and 18 had made a suicide attempt.

**The Clinical Picture in Childhood Depression** Childhood depression has been recognized as a diagnostic problem by a number of investigators (Herzog & Rathbun, 1982; Kashani et al., 1981b; Ryan et al., 1987). It includes behaviors such as withdrawal, crying, avoidance of eye contact, physical complaints, poor appetite, even aggressive behavior, and in some cases suicide (Rao et al., 1993).

Currently, childhood depression is classified using the mood disorder categories in the DSM-IV adult diagnostic system. This use of adult diagnostic depressive categories with children is considered to be appropriate by many. Lobovits and Handel (1985), for example, found that adult diagnostic categories could reliably be used with children. They conclude that the use of adult diagnostic criteria with children "offers a useful starting point for untangling the confusion surrounding the diagnosis and prevalence rate of childhood disorder" (p. 52).

**Causal Factors in Childhood Depression** The causal factors described in the childhood anxiety disorders are pertinent to the depressive disorders as well.

***Biological Factors.*** Research on affective disorders has focused attention upon a possible genetic component in child and adolescent depression. Clearly,

14.4

## Family Therapy and Play Therapy with Children

For a number of reasons, therapeutic intervention with children experiencing psychological problems is often a more complicated process than providing psychotherapy for adults. First, the source of a child's problem and the means for changing are often not within the child's power but instead are imbedded in the context of complex family interaction patterns. To remedy the child's problems, it is often necessary to alter those pathological family interaction patterns that produce or maintain the child's behavior. Second, even if the child's problems are viewed as primary and in need of specific therapeutic intervention, he or she may not be motivated for therapy or sufficiently verbal to gain understanding through psychotherapeutic methods that work with adults. Consequently, effective psychological treatment with children may involve using more indirect methods, such as treating an entire family in family therapy or providing individual psychological therapy for children in a less intrusive and more familiar way—through play in play therapy. We will examine these two approaches in more detail.

### Family Therapy

Several family therapy approaches have been developed (Minuchin, 1974; Patterson et al., 1992). These differ in some important ways, for example, in terms of how the family is defined (whether to include extended family members); what the treatment process will focus on (for example, whether communications between the family members or the "aberrant behavior" of the problem family members is the focus); what procedures are used in treatment (for example, analyzing and interpreting hidden messages in the family communications or altering the reward and punishment contingencies through behavioral assessment and reinforcement). Regardless of their differences, all family therapies view a child's problems, at least in part, as an outgrowth of pathological interaction patterns within the family, and they attempt to bring about positive change in family members through analysis and modification of the deviant family patterns.

How effective is family therapy at improving disruptive family relationships and promoting a more positive atmosphere for children? Hazelrigg, Cooper, and Borduin (1987), after comparing the research to date on family therapy, concluded that family therapy had positive effects when contrasted with no-treatment control samples or with alternative treatment approaches, such as individual therapy. In a recent meta-analytic study that included the results of 163 treatment trials, Shadish and colleagues (1993) found that the average therapy client was better off at termination than 70 percent of the clients in nontreatment conditions. They concluded that treatment outcome research strongly supported the effectiveness of family therapy.

### Play Therapy

As a treatment technique, play therapy emerged out of efforts to apply psychodynamic therapy to children. A number of factors limit the application of traditional psychodynamic therapy methods to children. Children do not voluntarily seek treatment and their motivation for self-change is different than for many troubled adults. They tend to be oriented to the present and lack the capability for insight and self-scrutiny that therapy requires. Their perceptions of their therapist differ from those of adult patients, and they may have an unrealistic view that the therapist can magically change their environment (Wenar, 1990).

Through their play, children often express their feelings, fears, and emotions in a direct and uncensored fashion, providing a clinician with a considerable means of understanding a child's problems and feelings. The activity of play has become a valuable source of obtaining personality and problem information about children. Psychodynamic techniques have been adapted for children by using play activity (in lieu of free association, used with adults) to enable a therapist to infer emotional conflicts, inappropriate affects, and excessive emotions a child might be experiencing. Play therapy sessions are usually centered on doll or puppet play to give a child a vehicle for expressing feelings. Other activities, particularly construction with different materials, such as play dough, crayons, and paper, are also used to encourage free expression.

In a play therapy session, the therapist usually needs to provide some structure or to guide play activities so that the child can express pertinent feelings. This might mean that the therapist asks direct questions of the child during the play session, such as: "Is the doll happy now?" or "What makes the doll cry?"

In addition to using play activity as a means of understanding a troubled child's problems, it also provides a medium for bringing about change in the child's behavior. A central process in play therapy is that the therapist, through interpretation, providing emotional support, and clarification of feelings (often by labeling them for the child), provides the child with a corrective emotional experience. That is, the therapist provides the child with an accepting and trusting relationship that promotes healthier personality and relationship development. The play therapy situation enables the child to reexperience conflict or problems in the safety of the therapy room, thereby providing a chance to conquer fears, to acclimate to necessary life changes, or to gain a feeling of security to replace the anxiety and uncertainty that had troubled him or her.

How effective is play therapy in reducing a child's problems and promoting better adjustment? When compared with adult treatment studies, play therapy compares quite favorably. Casey and Berman (1985) conducted a careful study of treatment research with children and concluded that such treatment "appears to match the efficacy of psychotherapy with adults" (p. 395). Play therapy was found to be as effective as other types of treatment, such as behavior therapy.

there appears to be an association between parental depression and behavioral and mood problems in children. Mufson, Weissman, and Warner (1992) found that children of parents with major depression were more impaired, received more psychological treatment, and had more psychological diagnoses than children of parents with no psychological disorders. The suicide attempt rate is higher for children of depressed parents (7.8 percent) than for the offspring of control parents (Weissman et al., 1992).

*Learning Factors.* Maladaptive learning appears to be important in childhood depressive disorders (Kaslow, Deering, & Racusin, 1994). Children who are exposed to negative parental behavior or negative emotional states may develop depressed affect themselves.

One important area of recent research is focusing on the mother-child interaction in the transmission of depressed affect. Specifically, investigators have been evaluating the possibility that mothers who are depressed, through their interactions with their infants, transfer their low mood to them. Depression among mothers is not uncommon and can result from several sources. Of course, many women who are clinically depressed have children. Some women, however, become depressed during pregnancy or following the delivery of their child. Several investigators have reported that marital distress, delivery complications, and difficulties with the infant are associated with depression in the mothers (Campbell et al., 1990; Sameroff, Seifer, & Zax, 1982).

Extensive research supports the view that the patterns of mother-infant behavior are critical to the development of attachment in a child (Egeland & Farber, 1984). Negative (depressed) affect and constricted mood on the part of a mother, manifested in unresponsive facial expressions and irritable behavior, can produce similar responses in her infant (Cohn & Tronick, 1983; Tronick & Cohn, 1989). Cohn and Campbell (in press) have shown that "infants respond in specific and characteristic ways to depressed maternal affect, and that these effects carry over to situations in which mothers no longer behave in a depressed way."

Cohn and colleagues (Cohn & Campbell, in press) have shown that when mothers interact with their depressed infants the children respond by turning away from them. Even nondepressed mothers, when trained to simulate a constricted-depressed interaction with their child, produce similar learned coping responses. Moreover, these infant coping responses persist even after the mother has stopped interacting with a "depressive" interaction style (Cohn & Tronick, 1983).

The extent to which an infant's negative response to a mother's depressed, constricted mood results in later childhood depression has not been fully determined. This research is highly suggestive, however, and may eventually lead to a fuller understanding of the possible link between a mother's mood and her child's behavior.

Another important line of research in childhood depression involves the cognitive-behavioral perspective. Considerable evidence has accumulated that "depressive symptoms are positively correlated with the tendency to attribute positive events to external, specific, and unstable causes and negative events to internal, global, and stable causes" (Garber & Hilsman, 1992; Hinshaw, 1992). For example, the child may learn to attribute peer rejection or teasing to a mistaken belief that he or she has some internal flaw. Hinshaw (1993) considers the tendency to develop distorted "mental representations" an important cause of disorders such as depression and conduct disorder.

**Treatments and Outcomes** The view that childhood and adolescent depression is like in kind to adult depression (Ryan et al., 1987) has prompted researchers to treat these mood disorders with medications such as imipramine and desimpramine that have worked with adult depression (Puig-Antich et al., 1985). The results, however, have not been very encouraging (Peterson et al., 1993; Ryan, 1992) in that some studies have failed to show antidepressant medication to be more effective than a placebo (Puig-Antich et al., 1985). Ambrosini and colleagues (1993), in their extensive evaluation of antidepressant medication treatment for children and adolescents, concluded that clinicians should not assume that children and adolescents will respond as adults to antidepressants.

More troublesome, however, are the undesirable side effects (i.e., nausea, headaches, nervousness, insomnia, and even seizures) that have been found to accompany use of antidepressant drugs with children and adolescents. Several accidental deaths have been reported for antidepressant medication; for example, the Medical Letter (1990) recently reported three deaths in children treated with normal dosages of desimpramine.

When depressed children and adolescents receive psychotherapy, treatment generally follows the model used with children suffering from anxiety disorders. An important facet of psychological therapy with children is providing a supportive emotional environment for them to learn more adaptive coping strategies and effective emotional expression. Older children and adolescents can often benefit from a positive therapeutic relationship in which they can discuss their feelings openly. Younger children or those with less developed verbal skills may benefit from play therapy. Controlled studies of psychological treatment with depressed adolescents have shown significantly reduced symptoms with psychological therapy (Kahn et al., 1990; Lewinsohn et al., 1990). Rawson and Tabb (1993) showed that short-term residential treatment was effective with depressed children ages 8–14 years of age.

An important aspect in the treatment of depression in young people is the necessity of a suicide appraisal (Berman & Jobes, 1991), as illustrated by the following case:

> Jack was admitted to a child psychiatric hospital unit after he attempted to stab himself in the stomach with a medium sized kitchen knife. The suicide attempt was foiled by his mother, who pulled the knife away from her son. This suicide attempt occurred immediately after Jack had an argument with his father. Jack felt that his "father hates me" and that "I would be better off dead." A variety of factors made Jack vulnerable to suicidal tendencies. Jack grew up in an atmosphere in which there was intense disagreement between his parents. His father drank heavily and when drunk would physically assault his mother. Jack's mother was chronically depressed and often said that "life is not worth living." However, she loved her son and felt that because he needed her, she must continue to work and manage the home. Jack has a serious learning disability, and he struggled to maintain his school grades. He had a private tutor who helped him overcome his sad feelings and shame. Often, when teased by his classmates, he thought about ending his life. (Pfeffer, 1985, pp. 218–19)

Depressed mood has come to be viewed as an important risk factor in suicide among children and adolescents (Posener, Le Haye, & Cheifetz, 1989; Rubenstein et al., 1989; Slap et al., 1989; Velez & Cohen, 1987). In fact, over 5000 American adolescents kill themselves each year (Youth Suicide in the United States, 1986), and suicide has tripled for individuals between the ages of 15 and 24 during the 1980s (Blumenthal, 1990). Children who attempt suicide are at greater risk for subsequent suicidal episodes than nonattempters, particularly within the first two years after their initial attempt (Pfeffer et al., 1994).

## Other Symptom Disorders

The behavior disorders we will deal with in this section—elimination disorders (enuresis and encopresis), sleepwalking, and tics—typically involve a single outstanding symptom rather than a pervasive maladaptive pattern.

**Functional Enuresis** The term **enuresis** refers to the habitual involuntary discharge of urine, usually at night, after the age of expected continence (age five). In DSM-IV, functional enuresis refers to bedwetting that is not organically caused. Children who have primary functional enuresis have never been continent; children who have secondary functional enuresis have been continent for at least a year, but have regressed.

Enuresis may vary in frequency, from nightly occurrence to occasional instances when a child is under considerable stress or is unduly tired. It has been estimated that some 4–5 million children and adolescents in the United States suffer from the inconvenience and embarrassment of this disorder. Estimates of the prevalence of enuresis reported in DSM-IV are 7 percent for boys and 3 percent for girls at age five; 3 percent for boys and 2 percent for girls at age ten; and 1 percent for boys and almost nonexistent for girls at age eighteen. Research has shown that there are clear sex differences in enuresis as well as age differences. In one extensive epidemiological study of enuresis in Holland, Verhulst and colleagues (1985) determined that between the ages of five and eight, enuresis is about two to three times more common among boys than among girls. The percentages for boys also diminish at a slower rate; the decline for girls between ages four and six is about 71 percent, while the decline for boys is only 16 percent. The authors recommend that the age criteria for boys' enuresis be extended to age eight because it is at about age nine that approximately the same percentage of boys as girls reach "dryness," that is, wetting the bed less than once a month.

Enuresis may result from a variety of organic conditions, such as disturbed cerebral control of the bladder (Kaada & Retvedt, 1981), neurological dysfunction (Lunsing et al., 1991), or other medical factors such as small functional bladder capacity and weak urethral spinchter (Dahl, 1992). One group of researchers reported that 11 percent of their enuretic patients had disorders of the urinary tract (Watanabe et al., 1994). However, most investigators have pointed to a number of other possible causal factors: (a) faulty learning, resulting in the failure to acquire a needed adaptive response—that is, inhibition of reflex bladder emptying; (b) personal immaturity, associated with or stemming from emotional problems; (c) disturbed family interactions, particularly those that lead to sustained anxiety, hostility, or both; and (d) stressful events (Haug Schnabel, 1992). For example, a child may regress to bedwetting when a new baby enters the family and becomes the center of attention. In adolescence, enuresis is often associated with other psychological problems. Research evidence supports a multiplicity of possible causes for enuresis, with many cases being explained by either environmental factors or maturational lags (Christie, 1981; Houts, 1991).

Medical treatment of enuresis typically centers on using medications, such as imipramine, in which the mechanism underlying the action of the drug is unclear but it may simply decrease the deepest stages of sleep to light sleep enabling the child to recognize bodily needs more effectively (Dahl, 1992). More recently, an intranasal desmopressin (DDAVP) has been used to help children "manage" urine more effectively. DDAVP, a hormone replacement, apparently "increases urine concentration, decreases urine volume, and decreases enuretic events" (Dahl, 1992). The use of medication to treat enuretic children is no panacea—the drugs appear to be effective only with a subset of enuretic children and then only temporarily. Dahl (1992) cautions that medications by themselves do not cure enuresis and that there is frequent relapse when the drug is discontinued or the child habituates to the medication.

Conditioning procedures have proved to be the most effective treatment of enuresis (Frimen & Warzak, 1990). Mowrer and Mowrer (1938) introduced a procedure in which a child may sleep on a pad that is wired to a battery-operated bell. At the first few drops of urine, the bell is set off, thus awakening the child. Through conditioning, the child comes to associate bladder tension with awakening. Fortunately, with or without treatment, the incidence of enuresis tends to decrease significantly with age. Nevertheless, many experts believe that enuresis should be treated in childhood because no way currently exists to identify which children will remain enuretic into adulthood. In a recent comparison and evaluation of research on the treatment of bedwetting, Houts, Berman, and Abramson (1994) concluded that treated children were more improved at follow-up than nontreated children. They also found that psychological treatment was more effective in reducing bedwetting than were physical treatments.

**Functional Encopresis** The term **encopresis** describes children who have not learned appropriate toileting for bowel movements after age four. This condition is less common than enuresis. However, about 2.3 percent of eight-year-old boys and 0.7 percent of eight-year-old girls are encopretic (Bellman, 1966). The following list of characteristics was provided by Levine (1976) from a study of 102 cases of encopretic children: The average age was seven, with a range from ages four to thirteen; about one-third of encopretic children were also enuretic; and a large sex difference was found, with about six times more boys than girls in the sample. Many of the children soiled their clothing when they were under stress. A common time was in the late afternoon after school; few children actually had this problem at school. Most of the children reported that they did not know when they needed to have a bowel movement.

Many encopretic children suffer from constipation; thus an important element in the diagnosis of the disorder involves a physical examination to determine whether physiological factors are contributing to the disorder. The treatment of encopresis usually involves both medical and psychological aspects (Dawson, Griffith, & Boeke, 1990). Levine and Bakow (1975) found that, of the encopretic children they studied who were treated by medical and behavioral procedures, more than half were cured—that is, no additional incidents occurred within six months following treatment. An additional 25 percent were improved.

**Sleepwalking (Somnambulism)** Though the onset of sleepwalking disorder is usually between the ages of 6 and 12, the disorder is classified broadly under sleep disorders in DSM-IV rather than under disorders of infancy, childhood, and adolescence. The symptoms of **sleepwalking disorder** involve repeated episodes in which a person leaves his or her bed and walks around without being conscious of the experience or remembering it later.

Statistics are meager, but one epidemiological study in Sweden reported that 40 percent of a random sample of children experienced sleepwalking episodes (Klackenberg, 1987). Children subject to this problem usually go to sleep in a normal manner but arise during the second or third hour of sleep. They may walk to another room of the house or even outside, and they may engage in complex activities. Finally they return to bed and in the morning remember nothing that has taken place.

While moving about, sleepwalkers' eyes are partially or fully open; they avoid obstacles, listen when spoken to, and ordinarily respond to commands, such as to return to bed. Shaking them will usually awaken sleepwalkers, and they will be surprised and perplexed at finding themselves in an unexpected place. Sleepwalking episodes usually last from 15 to 30 minutes. The risk of injury during sleepwalking is illustrated by the following case study:

> 14-year-old Donald Elliot got up from his bunk in his sleep, looked in the refrigerator, then, still asleep, walked out the back door. It would have been just another sleepwalking episode except that Donald was in a camper-pickup truck traveling 50 miles an hour on the San Diego freeway. Miraculously, he escaped with cuts and bruises. But his experience, and that of many other sleepwalkers, disproves one of the myths about somnambulism: that people who walk in their sleep don't hurt themselves. (Taves, 1969, p. 41)

The causes of sleepwalking are not fully understood. Kales and associates (1966) have shown that sleepwalking takes place during NREM (non–rapid eye movement) sleep. It appears to be related to some anxiety-arousing situation that has just occurred or is expected to occur in the near future (Klackenberg, 1987).

Little attention has been given to the treatment of sleepwalking. Clement (1970), however, has reported on the treatment of a seven-year-old boy through behavior therapy, as described in HIGHLIGHT 14.5. Nagaraja (1974) has reported the successful treatment of an eight-year-old boy and a nine-year-old girl with a combination of tranquilizers and psychotherapy. Nevertheless, a good deal of additional research is needed before we can deter-

14.5

## The Treatment of Sleepwalking Utilizing Conditioning Procedures

Bobby, a 7-year-old boy, walked in his sleep an average of four times a week. His mother kept a record indicating that Bobby's sleepwalking episodes were associated with nightmares, perspiring, and talking in his sleep. During the actual sleepwalking, Bobby usually was glassy-eyed and unsteady on his feet. On one occasion, he started out the front door. The sleepwalking had commenced about six weeks before the boy was brought for therapy. Usually an episode would begin about 45 to 90 minutes after he had gone to bed.

During treatment, the therapist learned that just before each sleepwalking episode Bobby usually had a nightmare about being chased by "a big black bug." In his dream, Bobby thought "the bug would eat off his legs if it caught him" (Clement, 1970, p. 23). Bobby's sleepwalking episodes usually showed the following sequence: After his nightmare began, he perspired freely, moaned and talked in his sleep, tossed and turned, and finally got up and walked through the house. He did not remember the sleepwalking episode when he awoke the next morning.

Assessment data revealed no neurological or other medical problems and indicated that Bobby was of normal intelligence. He was, however, found to be "a very anxious, guilt-ridden little boy who avoided performing assertive and aggressive behaviors appropriate to his age and sex" (p. 23). Assertiveness training and related measures were used but were not effective. The therapist then focused treatment on having Bobby's mother awaken the boy each time he showed signs of an impending episode. After washing Bobby's face with cold water and making sure he was fully awake, the mother would return him to bed, where he was "to hit and tear up a picture of the big black bug." (At the start of the treatment program, Bobby had made up several of these drawings.)

Eventually, the nightmare was associated with awakening, and Bobby learned to wake up on most occasions when he was having a bad dream. Clement considered the basic behavior therapy model in this case to follow that used in the conditioning treatment for enuresis, where a waking response is elicited by an intense stimulus just as urination is beginning and becomes associated with, and eventually prevents, nocturnal bedwetting.

mine the most effective treatment procedures for sleepwalking.

**Tics** A **tic** is a persistent, intermittent muscle twitch or spasm, usually limited to a localized muscle group. The term is used broadly to include blinking the eye, twitching the mouth, licking the lips, shrugging the shoulders, twisting the neck, clearing the throat, blowing the nose, and grimacing, among other actions. Tics occur most frequently between the ages of 6 and 14 (Schowalter, 1980). In some instances, as in clearing the throat, an individual may be aware of the tic when it occurs; but usually he or she performs the act habitually and does not notice it. In fact, many individuals do not even realize they have a tic unless someone brings it to their attention. The psychological impact tics can have on an adolescent is exemplified in the following case:

> An adolescent who had wanted very much to be a teacher told the school counselor that he was thinking of giving up his plans. When asked the reason, he explained that several friends had told him that he had a persistent twitching of the mouth muscles when he answered questions in class. He had been unaware of this muscle twitch and even after being told about it could not tell when it took place. However, he became acutely self-conscious and was reluctant to answer questions or enter into class discussions. As a result, his general level of tension increased, and so did the frequency of the tic, which now became apparent even when he was talking to his friends. Thus a vicious circle had been established. Fortunately, it proved amenable to treatment by conditioning and assertiveness training.

An extreme tic disorder involving multiple motor and vocal patterns is **Tourette's syndrome.** This disorder typically involves uncontrollable head movements with accompanying sounds, such as grunts, clicks, yelps, sniffs, or words. About one-third of individuals with Tourette's syndrome manifest *coprolalia,* which is a complex vocal tic involving the uttering of obscenities. The average age of onset for Tourette's syndrome is age 7, and most cases have an onset before age 14. The disorder is about three times more frequent among males. Although the exact cause of Tourette's syndrome is undetermined, evidence suggests an organic basis for the syndrome.

Most tics, however, do not have an organic basis but usually stem from psychological causes, such as self-consciousness or tension in social situations. As in the case of the adolescent boy previously described, an individual's awareness of the tic often increases the tension—and the tic. Tics have been successfully treated by means of drugs, psychotherapy, and conditioning techniques. Ollendick (1981) reported success in treating tics by using behavioral techniques of self-monitoring and overcorrection.

## PERVASIVE DEVELOPMENTAL DISORDER: AUTISM

We next turn our attention to one of the most puzzling and disabling disorders of childhood—**autism,** a developmental disorder that involves a wide range of problematic behaviors, including deficits in language, perceptual, and motor development; defective reality testing; and an inability to function in social situations. The following case illustrates some of the behaviors that may be seen in an autistic child:

> The boy is five years old. When spoken to, he turns his head away. Sometimes he mumbles unintelligibly. He is neither toilet trained nor able to feed himself. He actively resists being touched. He dislikes sounds and is uncommunicative. He cannot relate to others and avoids looking anyone in the eye. He often engages in routine manipulative activities, such as dropping an object, picking it up, and dropping it again. He shows a pathological need for sameness. While seated, he often rocks back and forth in a rhythmic motion for hours. Any change in routine is highly upsetting to him.

Autism in infancy and childhood was first described by Kanner (1943). It afflicts some 80,000 American children—about 4 children in 10,000—and occurs about four or five times more frequently among boys than girls (Ritvo et al., 1989; Schreibman & Koegel, 1975; Steffenburg & Gillberg, 1986; Werry, 1979). A recent epidemiological study of four regions of France reported similar rates, 4.9

per 10,000, with boys about two to one (Fombonne & du Mazaubrun, 1992). It is usually identified before a child is 30 months of age and may be suspected in the early weeks of life. Autistic children come from all socioeconomic levels, ethnic backgrounds, and family patterns. It was once believed that autism was more prevalent among families in upper-socioeconomic levels; however, this finding may have been due to the particular sampling methods used in earlier studies (Wing, 1980). A recent epidemiological survey (Ritvo et al., 1989) has supported the view that autism is not associated with parental education, occupation, racial origin, or religion.

## The Clinical Picture in Autistic Disorder

Autistic children form a heterogeneous population, with varying degrees of impairments and capabilities. In this section we will discuss some of the behaviors that may be evident in autism. A cardinal and typical sign is that a child seems apart or aloof from others, even in the earliest stages of life (Adrien et al., 1992). Mothers often remember such babies as never being "cuddly," never reaching out when being picked up, never smiling or looking at them while being fed, and never appearing to notice the comings and goings of other people. Typically, autistic children do not show any need for affection or contact with anyone, usually not even seeming to know or care who their parents are. Several recent studies, however, have questioned this view that autistic children are emotionally "flat." These studies (Capps et al., 1993; Sigman et al., 1992) have shown that autistic children do express emotions and should not be considered as having an apparent lack of emotional reaction as noted in traditional descriptions of the disorder.

The absence or severely restricted use of speech is characteristic of autistic children. Autistic children have been considered to have an "imitative deficit" and do not effectively learn by imitation (Smith & Bryson, 1994). This dysfunction might explain the characteristic absence or limited use of speech by autistic children. If speech is present, it is almost never used to communicate except in the most rudimentary fashion, as by saying "yes" in answer to a question or by the use of **echolalia** (parrot-like repetition of a few words). Although the echoing of parents' verbal behavior is found to a small degree in normal children as they experiment with their ability to produce articulate speech, persistent echolalia is found in about 75 percent of autistic children (Prizant, 1983). Some research has focused on trying to understand if echolalia in autistic children is functional. Prizant and Duchan (1981) analyzed echolalic verbalizations—previously believed to be meaningless—according to tone, latency, and other speech characteristics. They concluded that, far from being meaningless, these verbalizations could help clinicians or researchers understand the communicative and cognitive functioning of autistic children. Nevertheless, these utterances remain highly cryptic and are, of course, an inadequate substitute for true language functioning.

*Extreme withdrawal from others is typical of autistic children.*

The usual picture of an autistic child as lacking in language ability and being wholly withdrawn is probably oversimplified. Researchers have found that autistic children vary considerably in language skill and at least some autistic children do comprehend language, even though they may not use it to express themselves as other children do (Wetherby & Prizant, 1992).

Autistic children seem to actively arrange the environment on their own terms in an effort to exclude or limit variety and intervention from other people, preferring instead a limited and solitary routine. Autistic children often show an active aversion to auditory stimuli, crying even at the sound of a parent's voice. The pattern is not always consistent, however; autistic children "may at one moment be severely agitated or panicked by a very soft sound and at another time be totally oblivious to loud noise" (Ritvo & Ornitz, 1970, p. 6).

Self-stimulation is often characteristic of these children, usually taking the form of such repetitive movements as head banging, spinning, and rocking, which may continue by the hour. Other bizarre as well as repetitive behaviors are typical. Such behavior is well described by Gajzago and Prior (1974) in the case of a young autistic boy:

> A was described as a screaming, severely disturbed child who ran around in circles making high-pitched sounds for hours. He also liked to sit in boxes, under mats, and [under] blankets. He habitually piled up all furniture and bedding in the center of the room. At times he was thought deaf—though he also showed extreme fear of loud noises. He refused all food except in a bottle, refused to wear clothes, chewed stones and paper, whirled himself, and spun objects. . . . He played repetitively with the same toys for months, lining things in rows, collected objects such as bottle tops, and insisted on having two of everything, one in each hand. He became extremely upset if interrupted and if the order or arrangement of things were altered. (p. 264)

In contrast to the behavior just described, some autistic children are skilled at fitting objects together. Thus their performance on puzzles or form boards may be average or above. Even in the manipulation of objects, however, difficulty with meaning is apparent. For example, when pictures are to be arranged in an order that tells a story, autistic children show a marked deficiency in performance.

Although some have regarded autistic children as potentially of normal intelligence, this view has been challenged by a number of investigators who consider most of these children to be mentally retarded (American Psychological Association, 1994). Prior and Wherry (1986) reported that about three-fourths of autistic children were mentally retarded. Some autistic children, however, show markedly discrepant abilities, such as astounding memory capabilities, as Dustin Hoffman depicted in the movie *Rain Man*. In this context, Goodman (1972) described the case of an "autistic-savant" who showed unusual ability at an early age in calendar calculating (rapidly determining the day of any calendar date in history) as well as in other areas, such as naming the capitals of most states and countries and rapid calculation that allowed him to win a lot of money in Las Vegas. Nevertheless, his language development was severely retarded, and he showed the indifference to others and related symptoms characteristic of autistic children.

Much has been learned recently about the cognitive deficits of autistic children (Wenar, 1990). Compared with other groups of children on cognitive or intellectual tasks, autistic children often show impairment (James & Barry, 1981; Ritvo & Freeman, 1978; Schopler, 1983). Boucher (1981), for example, found autistic children significantly impaired on memory tasks when compared with both normal and retarded children. Whether this cognitive impairment is the result of actual organic brain damage or of motivational deficits has not been established. Koegel and Mentis (1985) have raised the possibility that the deficits result from motivational differences; they found that autistic children can learn and perform tasks at a higher level if motivation for a task is found and appropriate reinforcement is provided.

Many autistic children become preoccupied with and form strong attachments to unusual objects, such as rocks, light switches, film negatives, or keys. In some instances the object is so large or bizarre that merely carrying it around interferes with other activities. When their preoccupation with the object is disturbed—for example, by its removal or by attempts to substitute something in its place—or when anything familiar in their environment is altered even slightly, they may have a violent temper tantrum or a crying spell that continues until the familiar situation is restored. Thus autistic children are often said to be "obsessed with the maintenance of sameness." Furthermore, autistic children have been referred to as "negativistic" because they seemingly do not comply with requests. However, this observation has been questioned in a study by Volkmar, Hoder, and Cohen (1985). They found that, under the carefully structured and reinforcing conditions in a clinic setting, autistic children were not negativistic and generally complied with requests made by staff.

In summary, autistic children typically show difficulties in relationships to other people, in perceptual-cognitive functioning, in language development, and in the development of a sense of identity (L. K. Wing, 1976). They also engage in bizarre and repetitive activities, demonstrate a fascination with unusual objects, and show an obsessive need to maintain environmental sameness. This is indeed a heavy set of handicaps.

## Causal Factors in Autism

The precise cause or causes of autism are unknown. However, evidence has accumulated that defective genes or damage from radiation or other conditions during prenatal development may play a significant role in the etiologic picture (Abramson et al., 1992; Rutter, 1991b; Smalley, 1991). Evidence for a genetic contribution to autism comes from examining the risk for autism in the siblings of autistic children. The best estimates are that families with one autistic child show a 3–5 percent risk of a sibling being autistic as well. Although this figure may seem low in an absolute sense, it is in fact extremely high given that the population frequency of autism is approximately 5 in 10,000 (Smalley, 1991). Twin studies have also consistently shown higher concordance rates among monozygotic than among dizygotic twins, although all such studies are limited by small sample sizes given the extreme rarity of the disorder. Nevertheless, the conclusion from family and twin studies is that 80–90 percent of the variance in risk for autism is based on genetic factors, making it probably the most heritable of the various forms of psychopathology discussed in this text (Rutter, 1991b; Smalley, 1991). Nevertheless, the exact mode of genetic transmission is not yet understood, and it seems likely that relatives may also show an increased risk for other cognitive and social deficits that are milder in form than true autism (Smalley, 1991). In other words, there may be a spectrum of disorders related to autism.

It seems likely at this point that the disorder we call autism involves both multiple kinds of deficit (Goodman, 1989) and multiple etiologic pathways (Gillberg, 1990). Thus we should perhaps not expect to find large risk factors accounting for all autistic outcomes, nor even exceptional levels of consistency from one study to another where differing samples of autistic youngsters have been evaluated. Some investigators have pointed to the existence of a possible genetic defect—a fragile site on the X chromosome, referred to as the "fragile X syndrome" (Brown et al., 1986; Tsai & Ghaziuddin, 1992) that may occur in about 8 percent of autistic males (Smalley, 1991). In addition, 15–20 percent of males with the fragile X syndrome are also diagnosed with autism, further suggesting a link between the two syndromes. Nevertheless, there also appear to be differences between autism and the fragile X syndrome, suggesting that there are some qualitative differences between the two syndromes (Smalley, 1991). Even subtler constitutional defects may also exist in autism. Most investigators believe that autism begins with some type of inborn defect that impairs an infant's perceptual-cognitive functioning—the ability to process incoming stimuli and to relate to the world.

Sociocultural factors have also been postulated as causal elements in autism. In his early studies of childhood autism, Kanner (1943) concluded that an innate disorder in a child is exacerbated by a cold and unresponsive mother, the first factor resulting in social withdrawal and the second tending to maintain this isolation. Most investigators, however, have failed to find the parents of autistic children to be "emotional refrigerators" (Schreibman & Koegel, 1975; Wolff & Morris, 1971).

Clearly, much remains to be learned about the etiology of childhood autism. It appears most reasonable to suppose, however, that this disorder normally begins with an inborn defect or defects in brain functioning, regardless of what other causal factors may subsequently become involved.

## Treatments and Outcomes

Medical treatment of autistic children has often been tried but has not proven effective (Rutter, 1985). The drug most often used in the treatment of autism is haloperidol (Haldol) (Campbell, 1987), but the data on its effectiveness do not warrant use unless a child's behavior is unmanageable by other means (Sloman, 1991). Recently, the drug clonidine, an antihypertensive medication, has been used with reportedly moderate effects at reducing the severity of the symptoms (Fankhauser et al., 1992). However, no currently available medication reduces the symptoms of autism enough to encourage general use. We will thus direct our attention to a variety of psychological procedures that have been more successful in treating autistic children.

In an extensive study of autistic children who were mentally retarded, socially unresponsive, and behaviorally disturbed, Bartak and colleagues at the Maudsley Hospital in England obtained significant results with educational procedures. Children who were assigned to a structured treatment unit focusing on formal schooling showed greater progress than those placed in units stressing play therapy, either free or structured (Bartak & Rutter, 1973; Russell, 1975). As a result of this work, Bartak (1978) suggested a "qualified optimism" for the educational progress of autistic children. The best predictor of a positive outcome in the treatment of autism, according to Bartak and Rutter (1976), is intelligence.

Behavior therapy in an institutional setting has been used successfully in the elimination of self-injurious behavior, the mastery of the fundamentals of social behavior, and the development of some language skills (Lovaas, 1977; Powers, 1992; Williams, Koegel, & Egel, 1981). Lovaas (1987) reported highly positive results from a long-term experimental treatment program of autistic children. Of the treated children, 47 percent achieved normal intellectual functioning and another 40 percent attained the mildly retarded level. In comparison, only 2 percent of the untreated, control children achieved normal functioning and 45 percent attained mildly retarded functioning. These remarkable results did, however, require a considerable staffing effort, with well-qualified therapists working each child at least 40 hours per week for two years. Interestingly, studies on the effectiveness of behavior therapy with institutionalized children have found that children who were discharged to their parents continued to improve, whereas those who remained in an institution tended to lose much of what they had gained (Lovaas, 1977). Recently, Kamps and colleagues (1992) and Koegel and colleagues (1992) reported positive effects in programs designed to teach autistic children to imitate social interactions.

Some of the most impressive results with autistic children have been obtained in projects that involve parents, with treatment in the home preferable to hospital-based therapy (Rutter, 1985; Schopler, Mesibov, & Baker, 1982). Treatment "contracts" with parents specify the desired behavior changes in their child and spell out the explicit techniques for bringing about these changes. Such contracting acknowledges the value of the parents as potential change agents—in contrast with the previously held belief that the parents were somehow to blame for their child's disorder (Schopler, 1978). Perhaps the most favorable results are those of Schreibman and Koegel (1975), who reported successful outcomes in the treatment of 10 of 16 autistic children. These investigators relied heavily on the use of parents as therapists to reinforce normal behavior in their children. They concluded that autism is potentially a "defeatable horror."

It is too early to evaluate the long-term effectiveness of these newer treatment methods or the degree of improvement they actually bring about. The prognosis for autistic children, particularly for children showing symptoms before the age of two, is poor (Hoshino et al., 1980). Commonly, the long-term results of autism treatments have been unfavorable. A great deal of attention has been given recently to high-functioning autistic children (children who meet the criteria for autism yet develop functional speech). Ritvo and colleagues (1988) studied 11 parents whom they believed met diagnostic criteria for autism (they were identified through having had children who were autistic). These individuals had been able to make modest adjustments to life, hold down jobs, and get married. The outcome in autism is often problematic, however. Clarke and colleagues (1989) followed up five high-functioning autistic children and found that four of them later developed symptoms of psychosis.

One important factor limiting treatment success is the problems autistic children experience in generalizing behavior outside the treatment context (Handleman, Gill, & Alessandri, 1988). Children with severe developmental disabilities do not transfer skills across situations very well. Consequently, learned behavior in one situation does not appear to help them meet challenges in others. This important component needs to be addressed if training or treatment programs are to be successful. Changes in the law in 1990 with respect to providing services for disabled children (Public Law 101-476) assure equal access to an appropriate education in the least restrictive environment for all children. It is likely that more focus will be placed on integrating school-age children with autism into traditional learning environments.

At our present state of knowledge the long-term prognosis for many autistic children is still guarded. Even with intensive long-term care in a clinical facility, where gratifying improvements may be brought about in specific behaviors, children are a long way from becoming "normal." Gillberg and Schaumann (1981) have noted that some autistic children make substantial improvement during childhood, only to deteriorate, showing symptom aggravation, at the onset of puberty. In spite of a few remarkable cases of dramatic success, the overall prognosis for autistic children remains guarded. Less than one-fourth of the autistic children who receive treatment appear to attain even marginal adjustment in later life.

## PLANNING BETTER PROGRAMS TO HELP CHILDREN AND YOUTH

In our discussion of several problems of childhood and adolescence, we have noted the wide range of treatment procedures available, as well as the marked differences in outcomes. In concluding the chapter, we will discuss certain special factors associated with the treatment of children, the problem of child abuse, and the need for child advocacy and the rights of children, to prevent the occurrence of negative conditions that inhibit their optimal development.

## Special Factors Associated with Treatment for Children and Adolescents

Mental health treatment, psychotherapy, and behavior therapy have been found to be as effective with children and adolescents as with adults (Casey & Berman, 1985; Kazdin et al., 1990; Weisz et al., 1987; and Weisz, Weiss, & Donenberg, 1992). A number of special factors must be considered in relation to treatment for children and adolescents:

1. *The child's inability to seek assistance.* Most emotionally disturbed children who need assistance are not in a position to ask for it themselves or to transport themselves to and from child treatment clinics. Thus, unlike an adult, who can usually seek help, a child is dependent, primarily on his or her parents. Adults should realize when a child needs professional help and take the initiative in obtaining it. Sometimes, however, adults neglect this responsibility. Plotkin (1981) has pointed out: "Parents have traditionally had the right to consent to health services for their children. In situations where the interest of the parents and children differ the rule has had unfortunate consequences and has left treatment professionals in a quandary" (p. 121).

The law identifies four areas in which treatment without parental consent is permitted: (a) in the case of mature minors (those considered to be capable of making decisions about themselves); (b) in the case of emancipated minors (those living independently—away from their parents); (c) in emergency situations; and (d) in situations in which a court orders treatment. Many children, of course, come to the attention of treatment agencies as a consequence of school referrals, delinquent acts, or parental abuse.

2. *The need to recognize special vulnerabilities that children and youth might experience that place them at great risk for developing emotional problems.* Many families provide an undesirable environment for their growing children. Studies have shown that up to a fourth of American children may be living in inadequate homes. Disruptive childhood experiences have been found to be a risk factor for adult problems. For example, a recent epidemiological study (Susser, Moore, & Link, 1993) reported that 23 percent of newly homeless men in New York city reported a history of out-of-home care as children, and another study by Caudill and colleagues (1994) reported that clients with a parental history of substance abuse were at over twice the risk for antisocial personality disorders.

Children growing up in pathogenic homes are at a double disadvantage. Not only are they deprived from the standpoint of environmental influence on

*Family discord is often an important causal element in childhood psychopathology.*

their personality development (Crouch & Milner, 1993), but they also lack parents who will perceive their need for help and actively seek and participate in treatment programs. Inadequate or inattentive parenting can result in a failure to recognize serious signs of developing emotional problems.

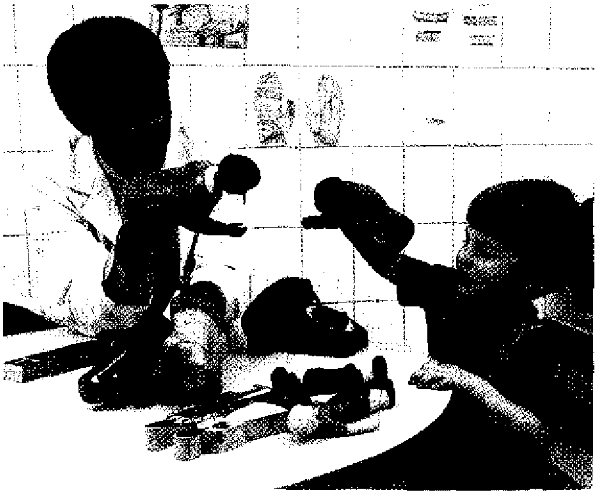
High-risk behaviors or conditions need to be recognized and taken into consideration (Kazdin, 1992). For example, there are a number of behaviors such as engaging in sexual acts, using alcohol or drugs, or delinquent behavior, that young people might engage in that place them at great risk for developing later emotional problems. Moreover, there are situations that can "happen" to young people, such as physical or sexual abuse, parental divorce, family turbulence, and homelessness, that place young people at great risk for emotional distress and subsequent maladaptive behavior.

3. *The need for treatment of the parents as well as the child.* Because many of the behavior disorders specific to childhood appear to grow out of pathogenic family interactions, it is often essential for the parents, as well as their child, to receive treatment. In some instances, in fact, the treatment program may focus on the parents entirely, as in the case of child abuse.

Increasingly, then, the treatment of children has come to mean family therapy, in which one or both parents, along with the child and siblings, may participate in all phases of the program. Many therapists discover that fathers are particularly difficult to engage in the treatment process. For working parents and for parents who basically reject the affected child, such treatment may be difficult to arrange (Gaudin, 1993), especially in the case of poorer families who lack transportation and money. Thus, both parental and economic factors help determine which emotionally disturbed children will receive assistance.

4. *The possibility of using parents as change agents.* In essence, the parents are trained in techniques that enable them to help their child. Typically, such training focuses on helping the parents understand the child's behavior disorder and learn to reinforce adaptive behavior while withholding reinforcement for undesirable behavior. Encouraging results have been obtained with parents who care about their children and want to help (Atkeson & Forehand, 1978; Forehand, 1993; Lexow & Aronson, 1975; Mash et al., 1976; O'Dell, 1974; Webster-Stratton, 1991).

5. *The problem of placing the child outside the family.* Most communities have juvenile facilities that, day or night, will provide protective care and custody for young victims of unfit homes, abandonment, abuse, neglect, and related conditions. Depending on the home situation and the special needs of the child, he or she will later either be returned to his or her parents or placed elsewhere. In the latter instance, four types of facilities are commonly relied on: foster homes, private institutions for the care of children, county or state institutions, or the homes of relatives. At any one time, over half a million children are living in foster-care facilities.



*Children can often express their feelings more directly through play than in words, as shown in this play therapy session.*

The quality of a child's new home, of course, is a crucial determinant of whether the child's problems will be alleviated or made worse. Although efforts are made to screen the placement facilities and maintain contact with the situation through follow-up visits, there have been too many reported cases of mistreatment in the new home.

In cases of child abuse, child abandonment, or a serious childhood behavior problem that parents cannot control, it has often been assumed that the only feasible action was to take the child out of the home and find a temporary substitute. With such a child's own home so obviously inadequate, the hope has been that a more stable outside placement would be better. But when children are taken from their homes and placed in an institution (which promptly tries to change them) or in a series of foster homes (where they obviously do not really belong), they are likely to feel rejected by their own parents, unwanted by their new caretakers, rootless, constantly insecure—and lonely and bitter.

Accordingly, the trend today is toward permanent planning. First, every effort is made to hold a family together and to give the parents the support and guidance they need for adequate childrearing. If this is impossible, then efforts are made to free the child legally for adoption and to find an adoptive home as soon as possible. This, of course, means that the public agencies need specially trained staffs with reasonable caseloads and access to resources that they and their clients may need.

6. *The importance of intervening early, before problems become acute.* Over the last 20 years, a primary concern of many researchers and clinicians has been to identify and provide early help for children who are at special risk. Rather than wait until these children develop acute psychological problems that may require therapy or major changes in living arrangements, psychologists are attempting to identify conditions in such children's lives that seem likely to bring about or maintain behavior problems and, where such conditions exist, to intervene before a child's development has been seriously distorted. An example of this approach is provided in the work of Wallerstein and Kelly (1980):

> These researchers identified children who were at risk for psychological disturbance as a result of their parents going through a divorce. Each of the 66 participating families was seen by a clinician, and the children were seen separately for several sessions. The goals of the counseling sessions were to provide the children with a means of expressing their worries and frustrations and to strengthen their resources for dealing with them.
>
> In addition to the counseling sessions, there were several follow-up sessions after the divorce to examine the psychological changes in the children and the changes in the family structure over time. The interventions were judged to be successful in lowering the tension levels in the family situations and in enhancing the children's adjustment to their new living arrangements.

Another type of early intervention has been developed in response to the special vulnerability children experience in the wake of disaster such as a hurricane, accident, or trauma such as a hostage-taking or shooting. Children and adolescents often require considerable support and attention to deal with traumatic events, a circumstance that is all too frequent in today's world. Individual and small-group psychological therapy might be implemented for victims of trauma (Gillis, 1993), support programs might operate thorough school-based interventions (Klingman, 1993), or community-based programs might be implemented, as in the period following the Hurricane Hugo disaster in Charleston, South Carolina (Joyner & Swenson, 1993). All of these efforts are aimed at providing immediate emotional support and problem resolution to reduce the posttraumatic symptoms and prevent the occurrence of long-term maladjustment problems (see the discussion on crisis intervention techniques in Chapter 18).

Such early intervention has the double goal of reducing the stressors in a child's life and strengthening the child's coping mechanisms. If successful, it can effectively reduce the number and intensity of later problems, thus averting problems for both the individuals concerned and the broader society. It is apparent that children's needs can be met only if adequate preventive and treatment facilities for children exist and are available to the children who need assistance. In the next section, we will look at the specific issue of child abuse, which is of growing concern to researchers and practitioners who want to know what causes it and how it can be prevented. In our final section, we will look at the leadership that government agencies have been providing in identifying the special needs of children and youth, and we will also discuss our society's responsibility to meet those needs.

## Child Abuse

The human species has a pretty dismal record when it comes to caring for its offspring. As DeMause (1990) pointed out:

> The history of humanity is founded upon child assault. All families once practiced infanticide. All states trace their origin to child sacrifice. All religions began with the mutilation and murder of children. All nations sanction the killing, maiming, and starving of children in wars and depressions. . . . Child assault is, in fact, humanity's most powerful and successful historical group-fantasy. Using children as scapegoats to relieve personal internal conflict has proved an extremely effective way to maintain our collective psychological homeostasis. Those

> who dare disturb this central group-fantasy run the risk of being declared guilty of impiety and considered disturbers of the world peace. . . . Historically, all cultures that have left records probably practiced widespread infanticide (p. 1–2)

In contemporary society, we deplore the idea that children were commonly mistreated in the past. Society's goals today encompass the ideals of kind and gentle treatment of our children and we collectively believe that the future of our society depends upon the proper care of our young. However, this lofty ideal is clearly not realized, as a growing and troublesome number of cases of child maltreatment makes clear. Child abuse is an increasing concern in the United States (Gelles & Cornell, 1990). A Department of Health and Human Services Report (House of Representatives, 1990) indicated that the numbers of children reported as abused and neglected rose 64 percent from 1980 to 1988, for an astounding total of 2.2 million cases of childhood maltreatment reported in 1988. Some evidence suggests that boys are more often physically abused than girls. It is usually clear that many children brought to the attention of legal agencies for abuse have been abused before (Kempe & Kempe, 1979; President's Commission on Mental Health, 1978).

In a survey of family violence, Gelles (1978) reported that violence well beyond ordinary physical punishment is widespread in parent-child relationships. Milder forms of punishment, Gelles found, were common among respondents; for example, 71 percent of parents reported having slapped or spanked their children, 46 percent reported pushing and shoving incidents, and around 10 percent reported having thrown something at their children. Gelles extrapolated estimates of serious violence from his survey to the general population and concluded that 46 percent of American children had suffered serious abuse, such as being kicked, bitten, or punched by parents.

The seriousness of the child abuse problem in our society was not realized until the 1960s, when researchers began to report case after case like the following two:

> The mother of a 29-month-old boy claimed he was a behavior problem, beat him with a stick and screwdriver handle, dropped him on the floor, beat his head on the wall or threw him against it, choked him to force his mouth open to eat, and burned him on the face and hands. After she had severely beaten him, the mother found the child dead.
>
> Because her 2½-year-old daughter did not respond readily enough to toilet training the mother became indignant and in a fit of temper over the child's inability to control a bowel movement gave her an enema with near scalding water. To save the child's life a doctor was forced to perform a colostomy (Earl, 1965).

Many abused children show impaired cognitive ability and memory when compared with control children (Friedrich, Einbender, & Luecke, 1983). In addition, abused children are likely to show problems in social adjustment and are particularly likely to feel that the outcomes of events are determined by external factors beyond their own control (Kinzl & Biebl, 1992; Toth, Manly, & Cicchetti, 1992). They are also more likely to experience depressive symptoms (Bushnell, Wells, & Oakley-Browne, 1992; Sternberg et al., 1992; Toth et al., 1992). Abused children are dramatically less likely to assume personal responsibility for themselves, and they generally demonstrate less interpersonal sensitivity than control children. Abused children also tend to show more self-destructive behavior than nonabused control subjects (Green, 1978), and physically abused children may be more likely to abuse their own children when they become parents (Malinosky-Rummel & Hansen, 1993). Childhood victimization was also found to be significantly related to the number of lifetime symptoms of antisocial personality disorder and predictive of a diagnosis of antisocial disorder in a recent study by Luntz and Widom (1994).

When the abuse involves a sexual component, such as incest or rape, the long-range consequences can be very marked (Kendall-Tackett et al., 1993). Individuals who have been sexually abused are more likely to develop substance abuse problems (Hernandez, 1992). Watkins and Bentovim (1992) reported that approximately 2–5 percent of men in the adult population have been sexually abused, often resulting in lifelong negative consequences such as sexual problems (e.g., exhibitionism, homophobic behavior, depression, anxiety) and even a tendency to recapitulate this experience as an adult. Jackson and colleagues (1990) found that women who had experienced intrafamily sexual abuse had significantly poorer social adjustment, especially in dating relationships. The women also reported significantly lower sexual satisfaction, more sexual dysfunctions, and lower self-esteem than control women. Adults who have been sexually abused as children often show serious psychological symptoms such as a tendency to use dissociative defense mechanisms to excess, excessive preoccupation with bodily functions, and lowered self-esteem (Nash et al., 1993).

The role of sexual abuse in causing psychological problems has recently been the subject of several longitudinal studies. A number of investigators have followed up sexually abused children to study the long-term effects of abuse on a victim's behavior. A large percentage of sexually abused children experience intense psychological symptoms following the incident (for example, 74 percent reported by Bentovim, Boston, & Van Elburg, 1987). At follow-up, however, the improvement often seems dramatic. Similarly, several other studies have reported substantial improvement of sexually abused victims at follow-up (Bentovim et al., 1987; Conte, Berliner, & Schuerman, 1986). One study found that 55 percent of victims had substantially improved at follow-up 18 months later, particularly in terms of sleeping problems, fears of the offender, and anxiety. However, 28 percent of the victims showed worsening behavior, such as family conflict and inappropriate attention seeking (Gomes-Schwartz, Horowitz, & Cardarelli, 1990).

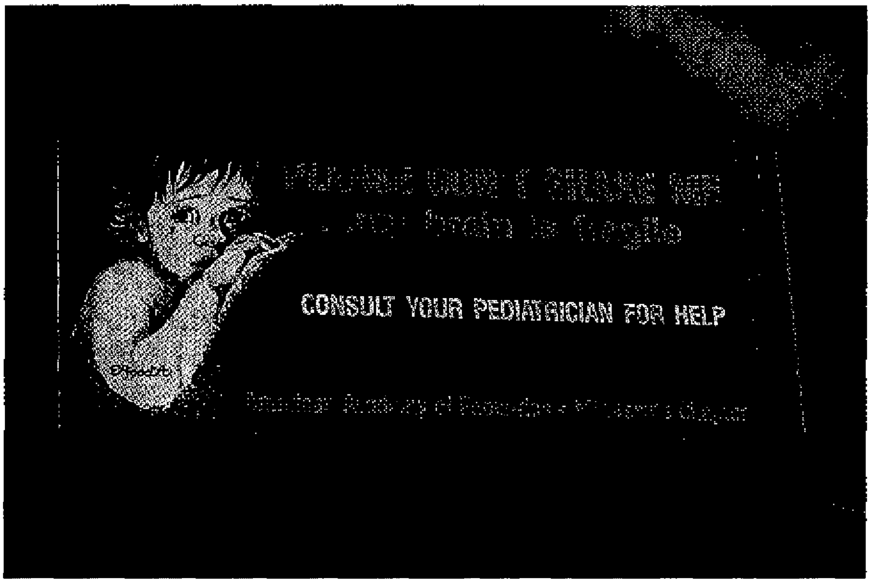
Several investigators have conceptualized the residual symptoms of sexual abuse as a type of post-traumatic stress disorder (PTSD) because the symptoms experienced are similar; for example, nightmares, flashbacks, sleep problems, and feelings of estrangement (Donaldson & Gardner, 1985; Frederick, 1986). However, other investigators (e.g., Finkelhor, 1990) object to this explanation on grounds that viewing these symptoms as an example of PTSD will "lead us to miss some of [the] most serious effects" of the sexual abuse experience such as prolonged depression or anxiety (p. 329).

**Causal Factors in Child Abuse** Since the 1960s, a great deal of research has been aimed at finding out which parents abuse their children and why, in the hope that ultimately these parents can be stopped, or better yet, prevented, from abusing their children. It is important to realize that in most cases it is not possible to find a single cause of child abuse. As Jay Belsky (1993) has pointed out, "There is no one pathway to these disturbances in parenting; rather, maltreatment seems to arise when stressors outweigh supports and risks are greater than protective factors" (p. 427). We now know that parents who physically abuse their children tend to be young, with most under 30. In most reported cases, they come from the lower-socioeconomic levels (Egeland & Erickson, 1990; Peterson & Brown, 1994). An important common factor among families with abusing parents is a higher-than-average degree of frustration; many stressors are present in their lives, including marital discord, high unemployment, and alcohol abuse (Egeland, Cicchetti, & Taraldson, 1976). Recent evidence suggests that levels of caregiver stress plays an important part in child abuse and neglect (Hillson & Kuiper, 1994). Many incidents of physical abuse occur as parental reactions to a child's misbehavior in areas such as fighting, sexual behavior, aggression, and so on (Herrenkohl, Herrenkohl, & Egolf, 1983). Although no clear and consistent personality pattern emerges as typical of child-abusing parents, they seem to show a higher-than-average rate of psychological disturbance (Serrano et al., 1979). Some evidence from personality testing shows that they tend to be aggressive, nonconforming, selfish, and lacking in appropriate impulse control (Lund, 1975).

**The Prevention of Child Abuse** Practitioners and child protection agencies have begun an extensive effort to reduce the amount and impact of child abuse. Their efforts include the following:

- Community education programs have been developed to increase public awareness of the problem. Television advertisements have been especially effective at sensitizing parents and children to potential abuse.
- Child protection teams have been organized by many state and county welfare departments to investigate and intervene in reported cases of child abuse.
- Teams of mental health specialists in many community mental health centers are working to evaluate and provide psychological treatment for both abused children and their parents.
- Parent support groups, often made up of former child abusers, are forming that can offer abusing parents or those at risk for child abuse alternative ways of behaving toward their children. All states require physicians and other professionals to report cases of child abuse that come to their attention.

One of the most effective treatment strategies for eliminating or reducing child abuse involves parent-focused interventions that include teaching parents clearly defined child training strategies



*Community education programs to increase public awareness of the problem of child abuse are but one of the current efforts to reduce the amount and impact of child abuse.*

aimed at improving child-rearing skills (Wolfe & Wekerle, 1993). Research aimed at enabling early intervention with parents identified as likely to abuse their children has been promising. Wolfe and colleagues (1988) identified women who were at high risk for maltreatment of their children. They randomly assigned mothers to either a treatment or a control group. The treatment consisted of behaviorally oriented parent training that provided child management skills, instruction in child care, modeling, rehearsal instructions to give clear, concise demands, and the use of "time out" as a punishment. The study showed that this early intervention reduced the risk for child abuse among the mothers provided the treatment. Through such efforts on many levels it is hoped that children will be spared abuse and that abusive or potentially abusive parents will be helped to be more effective and nurturant.

Unfortunately, child abuse all too frequently produces maladaptive social behavior in its victims. The treatment of abused children needs to address the problems of social adjustment, depression, and poor interpersonal skills that these children exhibit. An interesting treatment approach to reducing the negative consequences of child abuse is the use of peers to help modify abused children's tendency to withdraw and their poor social skills. Fantuzzo and colleagues (1988) trained peer confederates to make play overtures to abused children. They found that peer-initiated efforts were more effective at increasing the social interaction of withdrawn children than adult-initiated treatment efforts. Further work on rehabilitative efforts is needed to assist these unfortunate children in overcoming the psychologically disabling effects of being abused.

## Child Advocacy Programs

Today there are nearly 68 million people under age 18 in the United States (Spencer, 1989). Unfortunately both treatment and preventive programs for our society's children have been—and remain—inadequate. In 1970 the National Institute of Mental Health pointed out that fewer than 1 percent of the disturbed children in our society were receiving any kind of treatment, and less than half of those children were getting adequate help. In the same year, in its final report, *Crisis in Child Mental Health: Challenge for the 1970s,* the Joint Commission on the Mental Health of Children (1970) referred to our lack of commitment to our children and youth as a "national tragedy."

Unfortunately, eight years later, the President's Commission on Mental Health (1978) was still calling attention to the fact that children and adolescents were not receiving mental health services commensurate with their needs. The commission's report recommended again that greater efforts and financial resources be expended to serve the mental health needs of children and youth. It appears, however, that the needed financial support and redirected program focuses have not materialized in the years since the report was issued.

In 1989, the United Nations General Assembly adopted the UN Convention on the Rights of the

Child, which provides a detailed definition of the rights of children in political, economic, social and cultural areas. This international recognition of the rights of children can potentially have a great impact on promoting humane treatment of children (Wilcox & Naimark, 1991).

One approach in the United States that has been designed to meet mental health needs, mental health child advocacy, has been prominent in recent years. Advocacy programs attempt to help children or others receive services that they need but often are unable to obtain for themselves. In some cases, advocacy seeks to better conditions for underserved populations by changing the system (Meyers & Parsons, 1987; Roberts & Peterson, 1984).

Twice in recent years the federal government has established a National Center for Child Advocacy to coordinate the many kinds of work for children's welfare performed by different government agencies. Both times the new agency proved ineffective and was given up after a year or so. Currently, the fragmentation in children's services means that different agencies serve different needs; no government agency is charged with considering the whole child and planning comprehensively for children who need help.

Outside the federal government, until recently, advocacy efforts for children have been supported largely by legal and special-interest citizens' groups, such as the Children's Defense Fund, a public-interest organization based in Washington, D.C. Mental health professionals have typically not been involved. Today, however, there is greater interdisciplinary involvement in attempts to provide effective advocacy programs for children (Gentry & Eron, 1993; Hermalin & Morell, 1986).

Unfortunately, although such programs have made important local gains toward bettering conditions for mentally disabled children, a great deal of confusion, inconsistency, and uncertainty still persist in the advocacy movement as a whole (Levine & Perkins, 1987), and the need for improving the accountability of mental health services for children still exists (Burchard & Schafer, 1992). In addition, the mood at both federal and state levels has for some time been to cut back on funds for social services.

Clearly, the challenge issued in 1970 by the Joint Commission on the Mental Health of Children has not been adequately answered (Cohen et al., 1992) although some important beginning steps have been taken in the work toward child advocacy and new efforts to identify and help high-risk children have been made (National Advisory Mental Health Council, 1990). If the direction and momentum of these efforts can be maintained and if sufficient financial support for them can be procured, the psychological environment for children could substantially improve.

## UNRESOLVED ISSUES

### On Parental Pathology and Childhood and Adolescent Disorders

Do parents who are experiencing emotional problems transmit their problems to their children in some way? The evidence seems to be clear that children of disturbed parents are more vulnerable to developing psychological problems themselves than children of parents without emotional problems. For example, children of parents who were clinically depressed have been found to show poorer psychological functioning and more psychological disorders, including major depression, substance abuse, and internalization problems (Forehand, 1993; Gotlib & Colby, 1987; Weissman et al., 1987). Other emotional disorders in parents have also been found to be associated with emotional problems in children. For example, children of parents diagnosed with an anxiety disorder have been found to show more fears and more mood disturbance than children of control (community) parents (Turner, Beidel, & Costello, 1987). Parental pathology has also been found to be related to more conduct disorders in children (Dumas, Gibson, & Albin, 1989).

The actual mechanisms for the transmission of pathology from parent to child remain unclear. Researchers have noted, however, that it is not specific diagnoses among parents that result in specific disorders in children (Hammen et al., 1987), but the stress and symptoms that parents experience that influence children's behavior. Some research suggests that the mechanisms for causing behavior problems in children are to be found in learning processes. For example, maternal depression has been found to be associated with undesirable parenting practices, such as unresponsiveness, inattention, intrusiveness, inept discipline, and negative perceptions of children (Gelfand & Teti, 1990). Other researchers have pointed to family problems that create unfavorable emotional states; for example, tensions evolving from such incidents as parental divorce (Kornberg & Caplan, 1980) may produce psychological problems and achievement problems in youngsters (Bisnaire, Firestone, & Rynard, 1990).

Although emotionally upsetting events, such as divorce, are thought to cause childhood disorders, relationships between these and specific childhood psychopathology have not been documented. Some research has indicated that children suffer negative short-term and long-term effects of parental divorce (Amato & Keith, 1991; Wallerstein, 1991). Short-term effects include adjustment difficulties, low self-esteem, and higher rates of conduct disorders; long-term effects include shattered views of the world as a safe and reliable place, anger, and sexual promiscuity.

Recent evidence suggests that it is not divorce per se that produces disorder in a child—it is parental pathology. Lahey and colleagues (1988) found that parental divorce alone did not account for increased conduct disorder among boys. Rather, antisocial personality characteristics among parents were associated with conduct problems, suggesting that parental identification may be involved.

One extensive effort to understand the relationships between parental pathology and problems in children has been the Rochester longitudinal risk study (Sameroff et al., 1987). These investigators have followed up a sample of chronically ill schizophrenic women and their offspring to determine what, if any, impact their psychological problems and other possible risk factors (such as socioeconomic status, race, and family size) have on the development of behavior problems in their children. The women were initially assessed during their pregnancy and followed periodically since then. Their children have been evaluated over several periods since their birth. Sameroff and colleagues found that specific maternal diagnoses had the least impact on the development of behavior problems in the children. They reported that both socioeconomic status and the severity of the mother's illness had a greater impact on the child's developing problems. Children with multiple risk factors had much worse outcomes than children with fewer risk factors. The Rochester Adaptive Behavior Inventory (RABI) was used to obtain objective ratings of social-emotional competence on the children at the four-year follow-up. The risk variables studied were chronicity of illness, anxiety, parental education and occupation, interaction skill, minority status, family support, family size, and the presence of stressful life events. Children who received the lowest ratings on social and emotional competency tended to have the greatest risk for developing emotional problems (Sameroff et al., 1987). Generally, the more risk factors, the lower the children's ratings. The investigators also reported that although children of schizophrenic mothers are indeed at high risk for developing emotional problems, so too were children of severely ill mothers and those from poor and minority backgrounds.

Whether the transmission of psychopathology from parent to child is due to faulty learning processes, genetic transmission, or some combination of these and other factors, it seems clear that at least some childhood and adolescent disorders are related to parental psychopathology. The precise mechanism or mechanisms for the transmission itself remains for future research to untangle.

## SUMMARY

Traditionally, diagnosing behavior problems of children and adolescents has been a rather confused practice, in part because children have sometimes been viewed as "miniature" adults. It was not until the second half of the twentieth century that a diagnostic classification system focused clearly on the special problems of children.

Two broad approaches to the classification of childhood and adolescent behavior problems have been undertaken: a categorical approach, reflected most extensively in the DSM-IV, and a dimensional approach. Both classification approaches involve organized classes of observed behaviors. In the categorical approach, symptoms of behavior problems are grouped together as syndromes based on clinical observations. In the dimensional approach, a broad range of observed behaviors are submitted to multivariate statistical techniques; the symptoms that group together make up the diagnostic classes referred to as "dimensions."

In this chapter, the DSM-IV classification system is followed in order to provide clinical descriptions of a wide range of childhood behavior problems. Attention-deficit hyperactivity disorder is one of the more frequent behavior problems of childhood. In this disorder, the child shows impulsive, overactive behavior that interferes with his or her ability to accomplish tasks. There is some controversy over the explicit criteria used to distinguish hyperactive children from "normal" children or from children who exhibit other behavior disorders, such as conduct disorders. This lack of clarity in defining hyperactivity increases the difficulty of determining causal factors for the disorder. The major approaches to treating hyperactive children have been medication and behavior therapy. Using medications, such as amphetamines, with children is somewhat controversial. Behavior therapy, particularly cognitive-behavioral methods, has shown a great deal of promise in modifying the behavior of hyperactive children.

Another common behavior problem among children is that of conduct disorder. In this disorder, a child engages in persistent aggressive or antisocial acts. In cases where the child's misdeeds involve illegal activities, the terms *delinquent* or *juvenile delinquent* may be applied. A number of potential causes of conduct disorder or delinquent behavior have been determined, ranging from biological factors to personal pathology to social conditions. Treatment of conduct disorders and delinquent behavior is often frustrating and difficult; treatment is likely to be ineffective unless some means can be found for modifying a child's environment.

Another group of disorders, the childhood anxiety disorders, are quite different from the conduct disorders. Children who suffer from these disorders typically do not cause difficulty for others through their aggressive conduct. Rather they are fearful, shy, withdrawn, insecure, and have difficulty adapting to outside demands. The anxiety disorders may be characterized by extreme anxiety, withdrawal, or avoidance behavior. A likely cause for these disorders is early family relationships that generate anxiety and prevent the child from developing more adaptive coping skills. Behavior therapy approaches—such as assertiveness training and desensitization—may be helpful in treating this kind of disorder.

Several other disorders of childhood involve behavior problems centering on a single outstanding symptom rather than pervasive maladaptive patterns. The symptoms may involve enuresis, encopresis, sleepwalking, or tics. In these disorders, treatment is generally more successful than in the other disorders just described.

Finally, this chapter addressed one of the most severe and inexplicable childhood disorders—autism. In this disorder, extreme maladaptive behavior occurs during the early years and prevents affected children from developing psychologically. Autistic children, for example, seem to remain aloof from others, never responding to or seemingly not caring about what goes on around them. Many never learn to speak. These disorders likely have a biological basis, although definite proof of such a basis has proven elusive. Neither medical nor psychological treatment has been notably successful in fully normalizing the behavior of autistic children, but newer instructional and behavior-modification techniques have sometimes scored significant gains in improving their ability to function. In general, at present the long-term prognosis in autism appears discouraging.

A number of potential causal factors were considered for the disorders of childhood and adolescence. Although genetic predisposition appears to be important in several disorders, parental psychopathology, family disruption, and stressful circumstances, such as parental death or desertion and child abuse, can have an important causal influence. Recent research has underscored the importance of multiple risk factors in the development of psychopathology.

There are special problems, and special opportunities, involved in treating childhood disorders. The need for preventive and treatment programs for children is always growing, and in recent years the concept of child advocacy has become a reality in some states. Child abuse is a serious problem that has and continues to foster both research and clinical efforts into finding causes and devising preventive measures and treatment. Unfortunately, financial and other resources necessary for such services are not always readily available, and the future of programs for improving psychological environments for children remains uncertain.

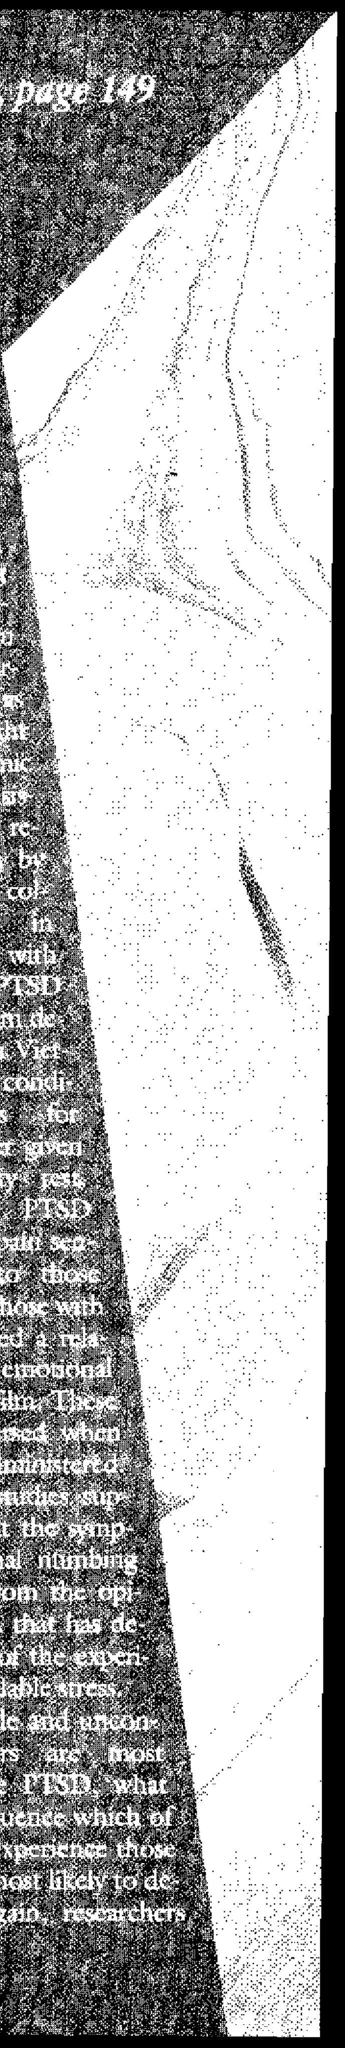
# CUTTING EDGE 1

# UNPREDICTABLE AND UNCONTROLLABLE STRESS AND PTSD



What features do the stressors known to cause PTSD have in common? Why do only some people who experience these stressors develop PTSD? Researchers in this area are looking increasingly at studies of stress in animals to answer these questions. For the past 30 years, extensive research in animals has shown that two of the most important determinants of how an organism responds to stress are whether the stressors are unpredictable or uncontrollable or both. An unpredictable stressor occurs without warning and its nature may be unforeseen. With an uncontrollable stressor, there is no way to respond to reduce its impact, such as by escape or avoidance. In general, both people and animals are more stressed by unpredictable and uncontrollable stressors than by stressors that are of equal physical magnitude but that are either predictable or controllable or both (e.g., Mineka & Hendersen, 1985).

These findings have not gone unnoticed by theorists and researchers interested in PTSD. Several investigators have noted many parallels in the symptoms of PTSD and the behavioral and physiological consequences of unpredictable and uncontrollable stress in animals (e.g., Basoglu & Mineka, 1992; Foa, Zinbarg, & Olasov-Rothbaum, 1992; Friedman, Charney, & Deutch, 1995; Mineka & Zinbarg, 1996, 1997). It is known, for example, that uncontrollable stress stimulates some noradrenergic brain systems and increases levels of central and peripheral norepinephrine (Friedman et al., 1995; Southwick, Yehuda, & Morgan, 1995). This led PTSD researchers to hypothesize that administration of a drug called *yohimbine* to persons with PTSD might increase their symptoms, because yohimbine is known to activate noradrenergic neurons. Consistent with this hypothesis, Southwick and colleagues (1993, 1995) found that 40 percent of a group of 20 veterans of the Vietnam War with PTSD experienced flashbacks when they took yohimbine; no control subjects without PTSD experienced flashbacks. In addition, the veterans with PTSD showed increases in other symptoms, such as intrusive traumatic thoughts, emotional numbing, and grief.

Uncontrollable stress in animals is also known to cause stress-induced analgesia (SIA), or diminished sensitivity to pain. Formerly neutral conditioned stimuli that are paired with uncontrollable stress can also become conditioned to elicit this analgesia. This SIA is known to work through the production of endogenous, or internally produced, opiate-like substances in the brain (Southwick et al., 1995; van der Kolk & Saporta, 1993). It can be reversed by the administration of a drug called *naloxone*, which is a biological antagonist of these opiate-like substances. PTSD researchers now believe that many of the symptoms of emotional numbing seen in people with PTSD may be caused by this same kind of SIA, rather than being a psychological defensive reaction against remembering the trauma (as previously thought by psychodynamic theorists). Consistent with this are results from a study by Pitman and his colleagues (1990) in which veterans with and without PTSD who watched a film depicting combat in Vietnam (certainly a conditioned stimulus for trauma) were later given a pain sensitivity test. Those with PTSD showed reduced pain sensitivity relative to those without PTSD. Those with PTSD also showed a relative blunting of emotional responses to the film. These effects were reversed when naloxone was administered. This and other studies support the idea that the symptoms of emotional numbing in PTSD stem from the opioid-mediated SIA that has developed because of the experience of uncontrollable stress.

If unpredictable and uncontrollable stressors are most likely to produce PTSD, what factors might influence which of the people who experience those stressors will be most likely to develop PTSD? Again, researchers have turned to the animal literature for answers (e.g., Mineka & Zinbarg, 1996, 1997). For example, it is known that prior experience with uncontrollable stressors can *sensitize* the organism, that is, make it more susceptible to the negative consequences of later experiences with uncontrollable trauma. Several studies of PTSD have confirmed that this is indeed the case, with victims of childhood abuse being more susceptible to PTSD in response to both sexual and nonsexual assault in adulthood (see Foa et al., 1992; Mineka & Zinbarg, 1996, 1997). In addition, soldiers who had been physically abused in childhood were more likely to develop PTSD during the Vietnam war (Bremner et al., 1993; Post, Weiss, & Smith, 1995).

By contrast, the animal literature also illustrates that the effects of uncontrollable stress can sometimes be *prevented* or minimized by prior experience with controllable stressors (see Mineka & Zinbarg, 1996, 1997). It is thought that experience with controllable stressors produces a sense of mastery that then allows the organism to cope better with subsequent uncontrollable stressors. This led Basoglu, Mineka and colleagues (in press) to hypothesize that the torture survivors in Turkey described on page 149 may not have shown very high rates of PTSD or other psychopathology because they were all political activists in Turkey during the time of a very repressive political regime. As political activists they had a greater sense of predictability and probably a greater sense of control regarding their torture experience than other people would have. This came from prior experience with similar stressors, stoicism training, knowledge about torture methods, and commitment to a cause. This may be why only 33% of these survivors had ever qualified for a diagnosis of PTSD in spite of the fact that these 55 people had experienced an average of 23 different forms of torture and an average of 291 total exposures to torture.

Recently a new sample of 34 torture survivors who were *not* political activists (but who were also not criminals) were interviewed and assessed using the same methods as in the study by Basoglu and coworkers (1994). These survivors of torture experienced significantly fewer different forms of torture, and over a much shorter period, than had the political activists. Yet they showed significantly more symptoms of PTSD and general psychopathology. Basoglu and colleagues (in press) hypothesized that this was because the nonactivist sample had a diminished sense of psychological predictability or immunization because their torture experience came "out of the blue," without any prior training in stoicism, any knowledge of torture methods, or commitment to a cause. The researchers developed a measure of "psychological preparedness for trauma" that assessed how well the survivors had been prepared and psychologically immunized before their torture experience. Not surprisingly, the political activist sample scored much higher on this measure of psychological preparedness than did the nonactivist sample. Of greatest interest, however, was the finding that, across the two studies, the single best predictor of the number of PTSD or general psychopathology symptoms the torture survivors exhibited was their degree of psychological preparedness; those who were more prepared showed fewer symptoms of PTSD and general psychopathology. In other words, psychological preparedness predicted symptoms better than did nine other variables, such as the number of torture events experienced, duration of detention, or time since last torture.

Increasing attention is being paid by PTSD researchers to studies of unpredictable and uncontrollable stress in animals. Considerable research now supports the hypothesis that perceptions of uncontrollability and unpredictability play an important role in the development and maintenance of PTSD symptoms. Moreover, the animal literature showing that prior experiences with uncontrollable stressors may sensitize an organism to the negative effects of subsequent experience with other uncontrollable stressors has led to important new findings regarding which individuals may be most susceptible to PTSD. Finally, the animal literature on predictability and immunization may help to explain why some people, such as the political activists who experienced extreme levels of torture, may show relatively low rates of PTSD.

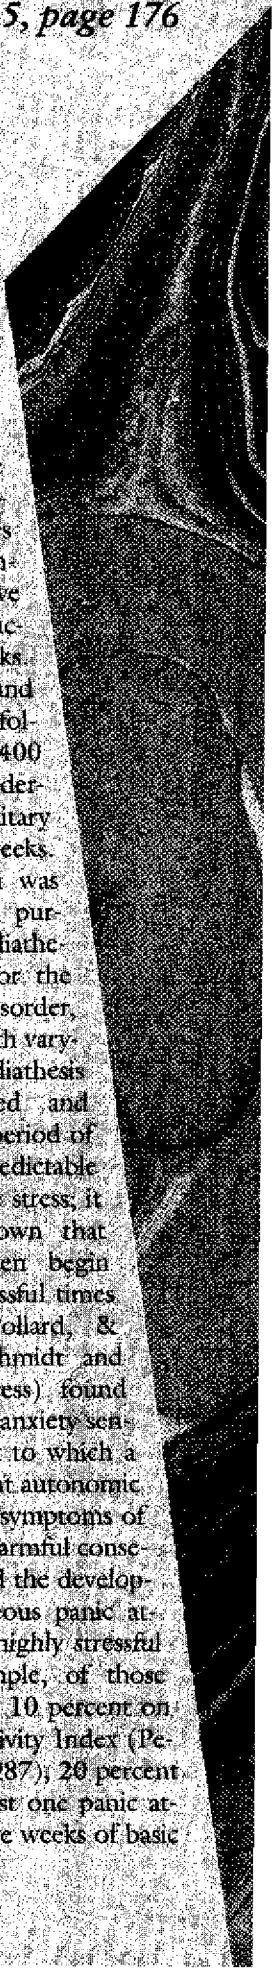
# CUTTING EDGE 2

## NEW FINDINGS ON AN "ANXIETY GENE" AND ON ANXIETY SENSITIVITY



In late 1996 scientists reported having identified a specific gene related to anxiety and neuroticism. This gene affects the brain's ability to use the neurotransmitter 5-hydroxytryptamine or serotonin, which has long been known to be involved in emotions as well as thinking processes. Indeed, many drugs now used to treat anxiety and depression are thought to work primarily through the effects they exert on the brain's serotonin system.

This is one of the first times that a specific gene has been identified that affects an important human personality trait—specifically, who is prone to anxiety and other negative moods and who is prone to a more stable, "laid-back" attitude. The gene affects what is called the *serotonin transporter*—molecules separate from serotonin itself that allow nerve cells to transport serotonin from the synaptic cleft into the nerve cell—usually "re-uptake" into the presynaptic neuron for storage and reuse (see Highlight 3.1, page 70). Researchers discovered that there are two important varieties of the gene—called 5-HTT (for 5HT transporter). The so-called long subtype has some extra DNA in it that the so-called short subtype lacks. Evidence indicates that the shorter version of the gene produces fewer serotonin transporter molecules, resulting in lower levels of serotonin uptake in certain key areas of the brain than occurs in people who have the longer version of the gene. Of greatest interest, however, is that people with the shorter version of the gene score significantly higher on scales measuring neuroticism or proneness to negative moods, such as anxiety, tension, sadness, and so on (Lesch et al., 1996).

The scientists emphasized that the size of the relationship between this transporter gene and neuroticism is quite small, accounting for only about 4 percent of the variance in people's neuroticism levels. Thus, many other, as yet unidentified, genes as well as experiential factors combine with this 5-HTT gene to determine a person's level of neuroticism (Goldman, 1996). Nevertheless, these findings are considered very important because neuroticism is one of the three or four most basic human personality dimensions (Watson, Clark, & Harkness, 1994) and because people with high levels of neuroticism are known to be at increased risk for both anxiety and depressive disorders (Clark, Watson, & Mineka, 1994). It is also of interest that about 70 percent of the 500 people studied had the short subtype of the gene. In other words, most of us have the more anxiety-prone gene. The search for specific genes related to other major psychiatric disorders, such as schizophrenia and bipolar disorder, has not yet been successful.

At about the same time that these findings on the anxiety gene were released, two other important new studies provided the best evidence to date that anxiety sensitivity (see pages 175–176) does indeed seem to serve as a vulnerability factor for panic attacks. Schmidt, Lerew, and Jackson (in press) followed over 1400 young adults undergoing basic military training for five weeks. The study design was excellent for the purpose of testing a diathesis-stress model for the onset of panic disorder, because people with varying levels of the diathesis were all followed and studied during a period of high levels of unpredictable and uncontrollable stress; it is fairly well known that panic attacks often begin during highly stressful times (e.g., Pollard, Pollard, & Corn, 1989). Schmidt and colleagues (in press) found that high levels of anxiety sensitivity (the extent to which a person believes that autonomic arousal and other symptoms of anxiety can have harmful consequences) predicted the development of spontaneous panic attacks during this highly stressful period. For example, of those scoring in the top 10 percent on the Anxiety Sensitivity Index (Peterson & Reiss, 1987), 20 percent experienced at least one panic attack during the five weeks of basic training; only 6 percent of the remaining study participants had a panic attack in the same period. Of those scoring in the top 25 percent on this index, 13 percent had at least one panic attack during this period, whereas of those scoring in the bottom 25 percent, only 3 percent panicked.

The high rates of panic attacks in those scoring high on anxiety sensitivity are particularly remarkable, because overall this sample of military cadets had very low levels of anxiety sensitivity compared with the general population (one could well imagine that most people high on anxiety sensitivity would be likely to avoid the military because of its unique demands and risks). It was also noteworthy that anxiety itself did not significantly predict who would panic—only *anxiety sensitivity* was a predictor. Moreover, anxiety sensitivity, but not anxiety, also served as a risk factor for functional impairment with peer and supervisory relationships, for poor physical health, and for poor overall performance.

In a second important study, Telch and his colleagues (1997) followed over 500 college students for one year, half of whom were high in anxiety sensitivity (but had never yet had a panic attack) and half of whom were low in anxiety sensitivity. At the end of the year, the students were interviewed to determine if they had experienced panic attacks during the year. Although these students were not undergoing the degree of stress that the military cadets were in the Schmidt et al. study (in press), the results were nonetheless quite similar. Nearly 10 percent of those in the high anxiety-sensitivity group had experienced at least one unexpected panic attack during the one-year follow-up period, whereas less than 4 percent of those in the low anxiety-sensitivity group had experienced an unexpected panic attack.

These studies provide by far the strongest evidence to date that anxiety sensitivity does seem to serve as a risk factor or diathesis for the development of panic and functional impairment from anxiety symptoms. Given this evidence that anxiety sensitivity serves as a diathesis for the development of panic attacks, prevention programs designed to reduce anxiety sensitivity in those at risk now become possible. It is known that cognitive-behavioral treatment for panic disorder itself reduces anxiety sensitivity (Mineka, Rozensky, & Martinovich, 1997; Telch et al., 1993), and so one would expect that similar procedures could be used to reduce anxiety sensitivity before people at risk ever develop panic attacks. One such ongoing prevention project is currently being conducted in Texas (Telch et al., 1997), so we should soon know not only whether a brief cognitive-behavioral intervention program given to those high in anxiety sensitivity can reduce anxiety sensitivity (Harrington et al., 1995) but also whether this translates into reduced vulnerability to panic attacks.

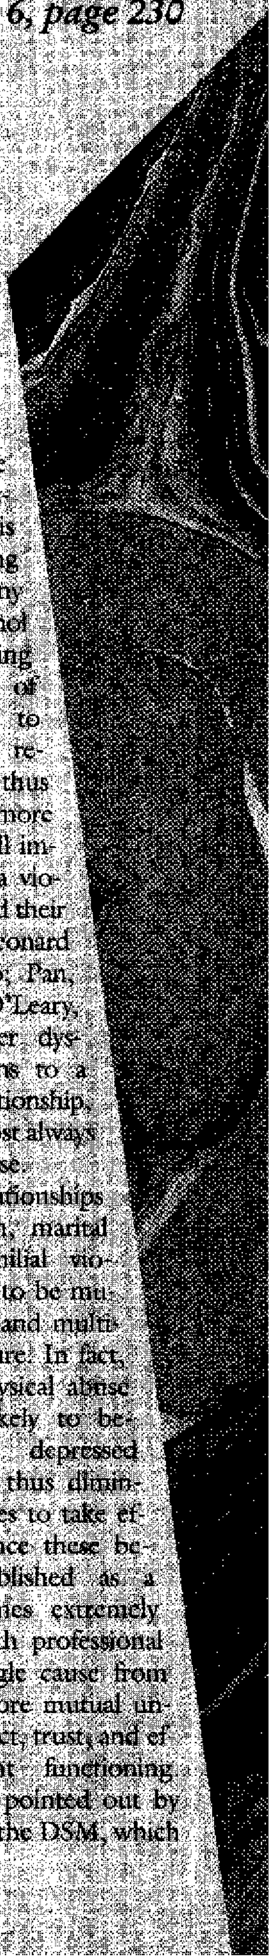
# CUTTING EDGE 3

# DEPRESSION AND DOMESTIC VIOLENCE



A strong concordance exists between distressed adult relationships and the presence of a mood disorder in one or both partners (Fruzzetti, 1996; Gotlib & Hammen, 1992; O'Leary, Christian, & Mendell, 1994). These forms of relationship distress may include the occurrence of violent abuse.

It has long been known that mood-disordered persons have an enhanced risk for engaging in violence, including family violence. Until fairly recently, however, virtually all of that enhanced risk was thought to be related to the lack of control and disinhibition associated with manic or hypomanic episodes. Continuing research developments, beginning in the 1980s (e.g., Maiuro et al., 1988), increasingly call that view into question and implicate depressive disorders in the occurrence of much violence, specifically domestic violence.

Men who attack their partners violently—some women also attack men, but usually less violently (Jacobson et al., 1994; O'Leary, 1995)—commonly do so as a means of attempting, by inspiring fear in the partner, to control a situation they perceive as threatening their "proprietary" assumptions about the partnership (e.g., Maiuro et al., 1988; Murphy, Meyer, & O'Leary, 1994; Wilson & Daly, 1996). Such men tend to be highly emotionally dependent on their partners, despite appearances to the contrary, and they tolerate poorly signs of a partner's autonomy. Their underlying sense of inadequacy fuels their desperate attempts to maintain control over the partnership. Too often, the result is a violent attack (Murphy, Meyer, & O'Leary, 1994).

A compelling example is provided in the notoriety attending the recent trials of former football superstar O. J. Simpson for the murder of his former wife, Nicole, and her friend Ron Goldman. Although the identity of the murderer may never be known "beyond a reasonable doubt," much evidence implicates Simpson. In any event, there is essentially no doubt that he was violently abusive toward his wife during and after their marriage, as described in a recent summary of the evidence by Meyer and Osborne (1996). These authors also make a convincing case that Mr. Simpson was in fact a prime example of the syndrome under discussion here, which includes a substantial component of painfully depressive symptoms.

Although it appears not to have been a factor in the Simpson case, many partnered men who experience marital distress and become depressed tend to be "unsuccessful," either chronically or in response to recent reversals of fortune. Self-perceived "failure," in terms of conventional male values such as providing for the economic needs of the family, is thus often a complicating factor (Pan, Neidig, & O'Leary, 1994; Vinokur, Price, & Caplan, 1996). Although these men frequently show evidence of high levels of "rejection sensitivity," their behavior in fact invites rejection, which increases the likelihood of heightened relationship friction (Downey & Feldman, 1996) and thus the further development of depressive symptoms (Fruzzetti, 1996). In this process of escalating dysphoria, many men turn to alcohol or other disinhibiting drugs as a type of "self-medication" to reduce stress and relieve depression, thus making it even more likely that they will impulsively attempt a violent solution to end their acute despair (Leonard & Senchak, 1996; Pan, Neidig, & O'Leary, 1994). Like other dysfunctional reactions to a deteriorating relationship, this one, too, almost always makes matters worse.

The causal relationships among depression, marital distress, and familial violence thus appear to be mutually reinforcing and multidirectional in nature. In fact, the victims of physical abuse are themselves likely to become clinically depressed (O'Leary, 1995), thus diminishing their abilities to take effective action. Once these behaviors are established as a pattern, it becomes extremely difficult, even with professional help, to disentangle cause from effect and to restore mutual understanding, respect, trust, and effective nonviolent functioning. Unfortunately, as pointed out by Fruzzetti (1996), the DSM, which recognizes disorders as exclusively "within" individuals, provides no adequate diagnostic recognition of this common scenario.

Despite the difficulties of establishing primacy within the entangled causal pattern in abusive relationships, contemporary research suggests that there is often evidence of problematic early attachment processes among the people involved. Deriving from the work of Bowlby (1980) in England, psychologists have in recent years developed apparently reliable and valid means of measuring adult attachment propensities (Griffin & Bartholomew, 1994), usually differentiating among three "levels" having significant implications for adult relationships. A person with a *secure* attachment pattern comfortably "connects with" and engages others at optimal levels of intimacy and mutual autonomy. *Insecure* attachment patterns include the *anxious-ambivalent*, involving high intimacy needs mixed with anxiety and conflicted, unstable attachments, and the *avoidant*, which involves an active distancing of the self from others. The general hypothesis advanced here is that partners with insecure attachment patterns, particularly the anxious-ambivalent variety, are at significantly increased risk for marital distress, depression, and domestic violence.

In support of this hypothesis, Woike, Osier, and Candela (1996) recently demonstrated a significantly high level of violent relationship imagery (male perpetrators, female victims) among anxious-attachment male college students. Anxious-attachment women in this study had more violent imagery, specifically involving female victims, than did secure or avoidant attachment women. The import of such findings, however, may go beyond mere violent imagery. Dutton and colleagues (1994) found evidence of disturbed attachment patterns in their sample of domestically violent men. Moreover, relationship difficulties associated with insecure attachment patterns may surface early in romantic pairing, as demonstrated by Simpson, Rholes, & Phillips (1996) in a study of college-age dating couples. In addition, Roberts, Gotlib, and Kassel (1996) have recently demonstrated what appears to be a causal relationship between attachment insecurity and the emergence of depressive symptoms, as mediated by self-esteem deficits. As already noted, depressive symptoms in the marital context are associated with a substantially enhanced risk of domestic violence, which sometimes proves deadly.

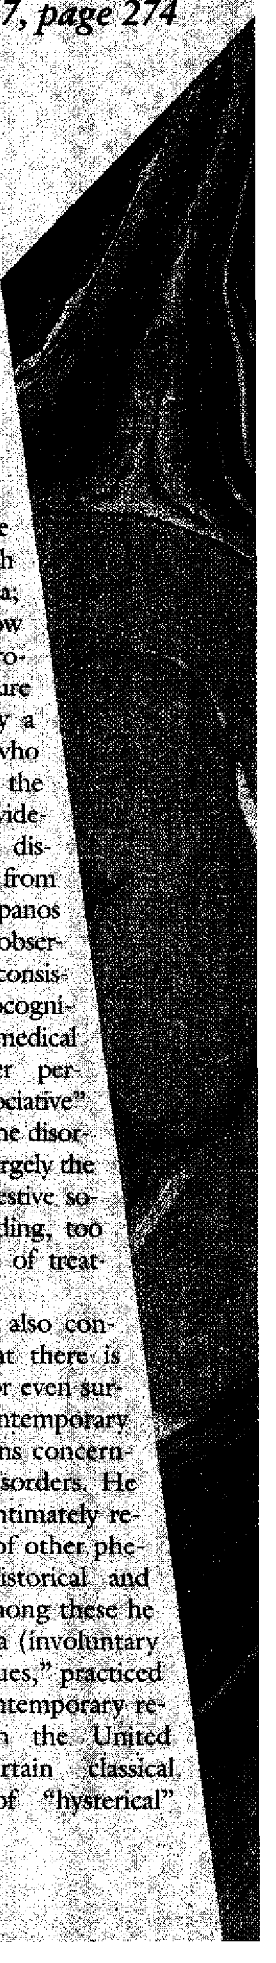
# CUTTING EDGE 4

# RECOVERED MEMORIES OF ABUSE AND DISSOCIATIVE DISORDERS: CONTINUING CONTROVERSY



Since the relevant chapter (7) was written the conflict between "believers" and "nonbelievers" has intensified regarding the clinical reality of Dissociative Identity Disorder (DID) and related phenomena, and the association of the latter with childhood experiences of abuse, particularly sexual abuse. To simplify, the major opponents in this conflict are the clinicians who try to "treat" these conditions and the more scientifically oriented mental health professionals who as a group doubt the validity of both the diagnosis and its alleged source in childhood abuse. With rare exceptions, evidence for the causal connection between DID and childhood abuse is restricted to "recovered memories" of adults being treated for dissociative experiences, thus inviting the criticism that false memories of abuse are implanted in the process of biased and erroneously conducted treatment.

Attempting to mediate on the issue of the validity of treatment-recovered memories, the American Psychological Association (APA) in 1994 convened a "balanced" panel of experts, the Working Group on the Investigation of Memories of Childhood Abuse. As one measure of the amount of dissent and controversy raging in this field, indications are strong that this group was unable over the many months of its existence to reach any consensus. Although some working group reports have been issued and more APA-sponsored documents are promised, there remains, in our judgment, little hope of achieving consensus on this issue at any time in the foreseeable future. As reported by the APA's Chief Executive Officer, Raymond Fowler (personal communication, February 27, 1997), "the working group agreed on almost nothing." The upshot is that the public remains entirely divided and confused as to what to believe about the validity of recovered memories of childhood abuse. This in turn means that the role such abuse might play in causing adult disorders, particularly those involving dissociative phenomena, is also extremely unclear.

The controversy has been sharpened by the recent posthumous publication of a notably provocative work, *Multiple identities and false memories*, by Nicholas Spanos (1996). In this book, Spanos, picking up on a theme of his own and of Krippner's (1994) already introduced in Chapter 7 reviews impressive evidence indicating that the occurrence of dissociative phenomena over time and place is markedly correlated with cultural and professional acceptance of these phenomena. He buttresses this argument by noting a bizarre distribution (significantly greater than chance would indicate) of cases of DID treated by various mental health clinicians. Most clinicians claim never or rarely to have encountered such clinical phenomena; the many cases now appearing in the professional literature are contributed by a few clinicians who strongly support the current notion of widespread dissociative disorder resulting from childhood abuse. Spanos argues that these observations are more consistent with a "sociocognitive" than with a medical or mental-disorder perspective on "dissociative" behavior. That is, the disordered behavior is largely the product of a suggestive social context, including, too often, the context of treatment for it.

Spanos (1996) also contests the idea that there is anything unique or even surprising about contemporary clinical observations concerning dissociative disorders. He regards them as intimately related to a variety of other phenomena, both historical and contemporary. Among these he includes glossolalia (involuntary "speaking in tongues," practiced among several contemporary religious groups in the United States) and certain classical demonstrations of "hysterical" disorder.

According to Spanos (1996), in short, DID is a type of self-absorbed role-playing inspired by popular culture and inadvertently reinforced and taught to vulnerable patients by well-meaning but misguided therapists specializing in the treatment of these conditions. Thus, patients who develop DID are unflatteringly described by Spanos as, typically,

> chronically disturbed, unhappy, polysymptomatic (usually female) people who are emotionally needy and who use displays of physical and psychological symptoms as a means of conveying their distress and gaining and maintaining the attention of their therapists and others (p. 259). . . . [DID is] a pattern of self-construal and interpersonal responding used by some troubled women to express dissatisfactions, "make sense" of their troubled lives, and attain some succor by adopting a variant of the sick role (p. 293).

We regard it as likely that Spanos's work will be passionately attacked by those committed to the view that DID and related phenomena are in every sense "real" mental disorders, and ones moreover that are for the most part the outcome of severe childhood sexual abuse. Unfortunately, passion—and the Spanos book is far from lacking in that quality—will not help in resolving the outstanding questions surrounding this field of inquiry, ones that have serious and widespread social implications. Although we find some of the phenomena often reported in recovered memories, such as lengthy, enforced participation in murderous satanic cults, as being almost without exception beyond belief, we are decidedly less certain about some of the more central issues that Spanos raises. These include, for example, the "reality" of DID as well as the purported role of early sexual abuse in causing pathological dissociation.

Lacking clear, unimpeachable evidence that would compel a consensus among responsible members of both the clinical and the scientific communities, our only reasonable recourse is to insist strongly that clinicians caring for persons suspected of having these conditions be held to the highest of professional standards of practice. There is widespread evidence of deviance from those standards, which is undoubtedly an important source of the impatience, irritation, and anger emanating from the more scientifically inclined in the mental health professions. To the extent that poor practice has resulted from ignorance and confusion, there is hope that the present unsatisfactory situation may be alleviated by a more informed and cautious approach.

A significant step forward in this regard is the recent appearance of still another book addressing this extremely complex clinical problem—*Recovered memories of abuse: Assessment, therapy, forensics*, by Kenneth Pope and Laura Brown (1996). The work is basically a "survival manual" for practitioners who are undaunted by the challenges this group of patients present and who venture to treat them. Unlike Spanos's (1996) offering, this book acknowledges the possibly "real" occurrence of DID and related clinical syndromes, as well as the possibility of a causal link between DID and childhood sexual abuse. It is also completely frank in confronting the contentious issues pervading the field and in recommending procedures that, if generally adopted, would lessen the likelihood of error on the part of overzealous practitioners.

The recommended approach of Pope and Brown (1996) emphasizes the importance of professional competence in three areas: intellectual, emotional, and procedural. The last of these refers to skill in "doing," in actually carrying out with expertise the elements of a carefully formulated assessment and treatment plan.

Intellectual competence, as the term implies, refers to the adequacy of the practitioner's knowledge of the basic psychological processes likely to be involved where possible abuse becomes an issue—such as memory functioning, developmental theory, and the nature and consequences of psychic trauma. Included here would be sophistication about the common pitfalls involved in developing inferences from observations, thus encouraging the practitioner to be self-critical in case formulation. Emotional competence refers to the practitioner's resilience in coping with the frequently dramatic clinical material that may come to light in working with patients who have recovered memories of abuse. The therapist who "loses it" in this regard is likely to make serious mistakes in case management. Pope and Brown recommend frequent consultation with professional colleagues, or in more serious instances perhaps even personal therapy, for practitioners who may themselves become at risk for engaging in aberrant professional behavior in working with this challenging clinical population.

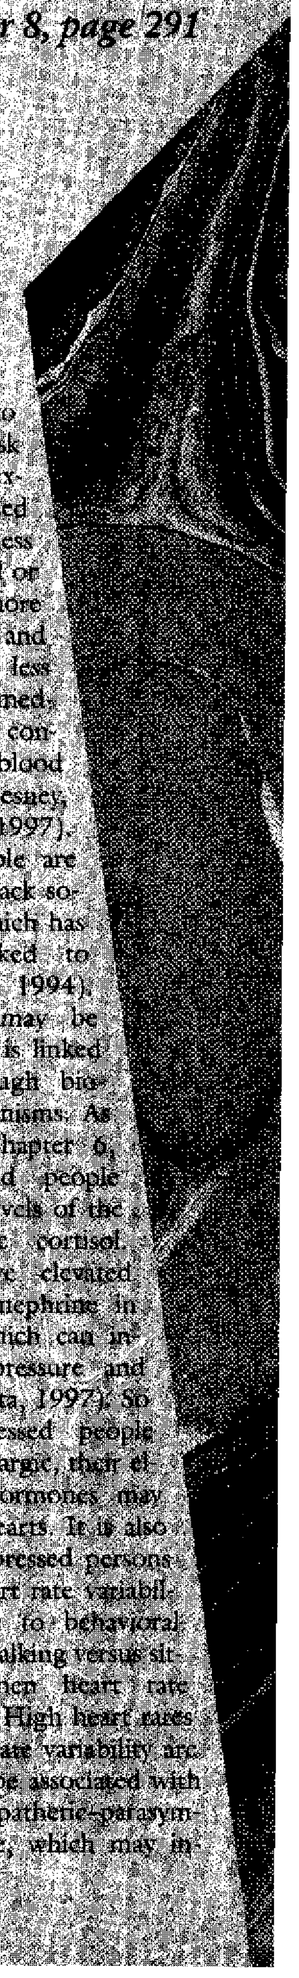
# CUTTING EDGE 5

# DEPRESSION AND CORONARY HEART DISEASE



Until the past few years the primary psychological variable recognized as affecting coronary heart disease (CHD) was Type A behavior—particularly the hostility component (see pages 288–292). Now, however, we are learning that depression also dramatically affects risk for CHD and has a negative effect on the progression of CHD once it has been diagnosed (Shapiro, 1996). At first it was noticed that people with heart disease were more likely to be depressed than were healthy people. Several studies have shown that 15 to 20 percent of people who have a heart attack are clinically depressed—a much higher figure than would be expected in the general population (Chesney, 1996; Shapiro, 1996). Such findings led investigators to examine the effects of depression on the course of CHD. Several studies now indicate that heart attack patients who are depressed at the time of their heart attack or shortly afterward show a greatly increased risk for future coronary events and cardiac death (Chesney, 1996; Shapiro, 1996). In their initial study, for example, Frasure-Smith, Lesperance, and Talajic (1993) followed 222 patients for six months who had had a heart attack. These investigators found that the clinically depressed patients were five times more likely to die in the next six months than were their nondepressed counterparts. Moreover, depression was as good a predictor of death from heart disease as were such medical variables as prior heart attacks or poor heart functioning. After adjusting for these other variables, they estimated that the relative risk of death associated with depression was still four times greater. Frasure-Smith and colleagues (1995) assessed these patients again 18 months after their initial heart attack and found that depression as assessed within 10 days of the initial heart attack was associated with a nearly eightfold increase in mortality (Shapiro, 1996). Ladwig, Roll, and Breithardt (1994) reached similar conclusions.

Other studies have shown that clinical depression is a *risk factor* for later developing CHD. For example, Pratt and her colleagues (1996) followed over 1500 men and women with no prior history of heart disease for 14 years. They found that 8 percent of those who had suffered major depression and 6 percent of those who had suffered mild depression at some point had a heart attack during the 14-year follow-up interval. By contrast, only 3 percent of those without a history of depression suffered heart attacks. When medical history and other variables were taken into account, those who had suffered major depression were found to be four times more likely to have had a heart attack. Similar findings had also been reported in several earlier studies (Chesney, 1996; Scheier & Bridges, 1995; Shapiro, 1996).

Two mechanisms have been proposed to explain the association between depression and CHD. The first is that depressed people may engage in more behaviors known to put people at risk for CHD. For example, depressed people are less likely to eat well or exercise, are more likely to smoke, and are perhaps less likely to take medications for such conditions as high blood pressure (Chesney, 1996; Kolata, 1997). Depressed people are also known to lack social support, which has also been linked to CHD (Eriksen, 1994).

Second, it may be that depression is linked to CHD through biochemical mechanisms. As discussed in Chapter 6, many depressed people have elevated levels of the stress hormone cortisol. They also have elevated rates of norepinephrine in their blood, which can increase blood pressure and heart rate (Kolata, 1997). So although depressed people may appear lethargic, their elevated stress hormones may damage their hearts. It is also known that depressed persons show lower heart rate variability in response to behavioral changes (e.g., walking versus sitting down when heart rate *should* change). High heart rates and low heart rate variability are also known to be associated with changes in sympathetic-parasympathetic balance, which may increase cardiac arrhythmias that often precede sudden death (Chesney, 1996; Frasure-Smith et al., 1993).

Given the high levels of comorbidity between anxiety and mood disorders discussed in Chapter 6, it is not surprising that a similar link might also be found between anxiety and CHD. Several studies suggest such a relationship. For example, De Silva (1993) found that patients with established CHD (e.g., coronary artery disease, angina, or prior heart attack) were at increased risk for sudden death when exposed to anxiety-provoking stressors. A recent study by Leor, Poole, and Kloner (1996) found a transient fivefold increase in sudden cardiac death in the days immediately following a 1994 California earthquake. The deaths were associated primarily with the emotional stress caused by the earthquake (Shapiro, 1996). Another study has documented a relationship between phobic anxiety and increased risk for sudden cardiac death. Kawachi and colleagues (1994a) followed nearly 34,000 male professionals for two years who had been assessed for panic disorder, agoraphobia, and generalized anxiety. Men with the highest levels of phobic anxiety were three times more likely to have a fatal heart attack than were men with the lowest levels of phobic anxiety. Sudden cardiac death was six times higher in the men with the highest levels of anxiety. However, there was *no* association found between anxiety and *nonfatal* attacks. The findings were replicated in a second study of nearly 2300 men who were participating in a normative aging study (Kawachi et al., 1994b, 1996).

Given these strong associations between depression (and anxiety) and risk for CHD, increasing attention is being paid to the need for treatment interventions. Most people with clinical depression are untreated, unnecessarily increasing their risk for CHD. Of those with major depression at the time of a heart attack, approximately one-half remain depressed or have relapsed one year later without treatment (Hance et al., 1996). Yet there is promising evidence that various treatments can help heart attack patients who are depressed. Linden, Stossel, and Maurice's (1996) review of the literature on psychosocial interventions for depression in CHD patients found good evidence that psychosocial interventions can decrease depression, systolic blood pressure, heart rate, and cholesterol levels. Moreover, patients who did not receive psychosocial treatment were 1.7 times more likely to die from their CHD, and 1.8 times more likely to have another heart attack in a two-year follow-up period than were patients who were treated for their depression and anxiety. Drug treatments are also considered more promising than in the past because the new class of antidepressants—the SSRIs (see Chapters 6 and 16)—are not contraindicated for patients with CHD as older tricyclic antidepressants often were (Chesney, 1996; Shapiro, 1996). Finally, at least one study has shown that cardiac rehabilitation and exercise programs that are frequently suggested to patients who have had a heart attack to improve their physical condition also significantly improves depression (Milani, Lavie, & Cassidy, 1996).

Fortunately, the findings reviewed here have not gone unnoticed by researchers at the National Heart, Lung, and Blood Institute of the National Institutes of Health. A very large study is now being conducted of 3000 heart attack patients at eight clinical sites across the United States to investigate whether interventions directed at decreasing depression immediately after a heart attack actually reduce the risk of future heart attacks and cardiac death. This is one more indication of the influence that behavioral medicine is having on drawing attention to the importance of psychological rather than purely medical variables in prevention of the leading cause of death in the United States today.

THE INTEGRATION OF ASSESSMENT DATA
UNRESOLVED ISSUES ON THE USE OF COMPUTERIZED ASSESSMENT
SUMMARY
KEY TERMS

A patient's "presenting complaint" to a clinician usually initiates a process of assessment, whereby the clinician attempts to understand the nature and extent of the problem for which help is being sought. At times this process of inquiry is convoluted and challenging, reminiscent of a Sherlock Holmes exercise in inductive and deductive logic. On other occasions assessment is a relatively straightforward matter in which the clinician may, with a high probability of being correct, come to a rapid conclusion about the basis for the complaint and the proper disposition of the case. Pediatricians whose practices tend to be confined to a local clientele, for example, know what childhood infections are "going around" at a given time. A child who has complaints that mimic the characteristic symptom profile for a common infection will likely be found to have that disease. Even so, the conscientious pediatrician will usually want to confirm an initial diagnostic impression with lab studies that identify the infectious organism involved before initiating specifically targeted treatment.

Confirming diagnostic impressions is thus a matter of good practice even in the most routine clinical situations. For the mental health practitioner, few clinical situations are as routine as our pediatric example, and adequate techniques for confirming initial impressions may prove far more elusive. With rare exceptions, the "lab work" essential to much medical assessment is irrelevant in this domain. Psychological disorders usually lack identifying biological characteristics. Furthermore, they are always interlaced with the personalities of the individuals suffering them and usually with the entire surrounding social fabric. Every instance is likely to be the product of a complex organization of contributing factors, many of which may not be apparent either immediately or after many months of intense scrutiny in the course of psychotherapy. As this last statement implies, psychological assessment or diagnosis can be an ongoing process that proceeds along with, rather than only preceding, treatment efforts.

In addition, as we have seen in earlier chapters, even where a specific diagnosis may be confidently determined, it will normally provide little of direct clinical significance beyond a descriptive summary of the behavioral observations the clinician has been able to make. It will not reveal, as do most medical diagnoses, the underlying pathologic processes producing the condition (for example, fever) that is observed. For these reasons the assessment of mental disorders is usually more difficult, more uncertain, and more protracted than it is for physical diseases.

It is no less critically important, however. No rational, specific treatment plan can be instituted without at least some general notion of what problems need to be addressed. As treatment proceeds, it is guided by the clinician's continuing assessment of the client's problems.

We will focus in this chapter on procedures especially appropriate to an initial clinical assessment, where an attempt is made to identify the main dimensions of a client's problem and to predict the likely course of events under various conditions. It is at this initial stage that crucial decisions have to be made—such as what if any treatment approach is to be offered, whether the problem will require hospitalization, to what extent family members will need to be included as co-clients, and so on. Sometimes these decisions must be made quickly, as in emergency conditions, and without recourse to critical information that would probably (but not necessarily) become available with extended client contact. As will be seen, various psychological measurement instruments are employed to maximize assessment efficiency in this type of pretreatment examination process (Gaw & Beutler, 1995).

A less obvious but equally important function of pretreatment assessment is that of establishing baselines for various psychological functions so that the effects produced by treatment can be measured. Criteria based on these measurements may be established as part of the treatment plan, such that the therapy is considered successful and is terminated only when the client's behavior meets these predetermined criteria. Also, as will be seen in Chapters 16 and 17, comparison of posttreatment with pretreatment assessment results is an essential feature of many research projects designed to evaluate the efficacy of various therapies.

Two other relatively common applications of psychological assessments will also be described in this chapter. The first application, involving determining whether an individual is experiencing psychological adjustment problems, centers on the use of psychological tests in court testimony. The second variant of this pretreatment assessment is the use of psychological assessment instruments in screening candidates for various roles and occupations. Here the effort is basically one of identifying persons who appear to be psychologically unfit (or, alternatively, highly suited) for the type of assignment or work sought. For example, a police recruit who appears to have uncertain control of anger and aggressive impulses may need to be counseled about possibly adopting another occupational goal, or about seeking therapy to remedy a lack of control that could be dangerous in an occupation involving both great stress and constant access to lethal weapons.

In this chapter, we will review some of the more commonly used assessment procedures and show how the data obtained can be integrated into a coherent clinical picture for use in making decisions about referral and treatment. Our survey will include a discussion of neuropsychological assessment, the clinical interview, behavioral observation, and personality assessment through the use of projective and objective psychological tests.

Let us look first at what, exactly, a clinician is trying to learn during the psychological assessment of a client.

## THE INFORMATION SOUGHT IN ASSESSMENT

What does a clinician need to know? First, of course, ***the problem must be identified.*** Is it a situational problem precipitated by some environmental stressor, a manifestation of a more pervasive and long-term disorder, or is it perhaps some combination of the two? Is there any evidence of recent deterioration in cognitive functioning? What is the duration of the current complaint and how is the person dealing with the problem? What, if any, prior help has been sought? Are there indications of self-defeating behavior and personality deterioration, or is the individual using available personal and environmental resources in a good effort to cope? How pervasively has the problem affected the person's performance of important social roles? Does the individual's symptomatic behavior fit any of the diagnostic patterns in the DSM-IV?

As we have seen, there has been a trend against overdependence on diagnostic labeling, particularly since a diagnosis provides only a limited perspective on a patient's problems. On the other hand, it is often important to have an adequate classification of the presenting problem for a number of reasons. In many cases, a formal diagnosis is necessary before insurance claims can be filed. Clinically, knowledge of a person's type of disorder can help in planning and managing the appropriate treatment. Administratively, it is essential to know the range of diagnostic problems that are represented among the patient or client population and for which treatment facilities need to be available. If most patients at a facility have been diagnosed as having personality disorders, for example, then the staffing, physical environment, and treatment facilities should be arranged accordingly. Thus, the nature of the difficulty needs to be understood as clearly as possible, including a categorization if appropriate.

For most clinical purposes, a formal diagnostic classification per se is much less important than having *a basic understanding of the individual's history, intellectual functioning, personality characteristics, and environmental pressures and resources.* That is, an adequate assessment includes much more than the diagnostic label. For example, it should include an objective description of the person's behavior. How does the person characteristically respond to other people? Are there excesses in behavior, such as eating or drinking too much? Are there notable deficits, as, for example, in social skills? How appropriate is the person's behavior? Is the person manifesting behavior that would be acceptable in some contexts but is often displayed where it is plainly unresponsive to the situation or to reasonable social expectations? Excesses, deficits, and appropriateness are key dimensions to be noted if the clinician is to understand the particular disorder that has brought the individual to the clinic or hospital.

In addition, assessment needs to include *a description of any relevant long-term personality characteristics.* Has the person typically responded in deviant ways to particular kinds of situations, for example, ones requiring submission to legitimate authority? Do there seem to be personality traits or behavior patterns that predispose the individual to behave in maladaptive ways across a broad range of circumstances? Does the person tend to become enmeshed with others to the point of losing his or her identity, or is he or she so self-contained that intimate exchange is routinely aborted? Is the person able to accept help from others? Is the person capable of genuine affection, or of accepting appropriate responsibility for others' welfare? Such questions are necessarily at the heart of many assessment efforts.

It is also important to assess *the social context in which the individual operates.* What kinds of environmental demands are typically placed on the person, and what supports or special stressors exist in his or her life situation? For example, being the primary caretaker for a spouse suffering from Alzheimer's disease is sufficiently challenging that relatively few can manage the task without significant psychological impairment, especially where outside supports are lacking. As we have seen, the DSM-IV classification includes guidelines for rating both the severity of the stressors in a person's current environment and the level of a person's overall adjustment in meeting the demands of a complex social environment.

The diverse and often conflicting bits of information about the individual's personality traits, behavior patterns, environmental demands, and so on must then be integrated into a consistent and meaningful picture. Some clinicians refer to this picture as a **dynamic formulation,** because it not only describes the current situation but includes hypotheses about what is driving the person to behave in maladaptive ways. At this point in the assessment, the clinician should have a plausible explanation, for example, for why a normally passive and mild-mannered man suddenly flew into a rage and started breaking up furniture.

The formulation should *allow the clinician to develop hypotheses about the client's future behavior* as well. What is the likelihood of improvement or deterioration if the person's problems are left untreated? Which behaviors should be the initial focus of change, and what treatment methods are likely to be most efficient in producing this change? How much change might reasonably be expected from a particular type of treatment?

Where feasible, decisions about treatment are made collaboratively with the consent and approval of the individual. In cases of severe disorder, however, they may have to be made without the patient's participation or in rare instances even without consulting responsible kin. As has already been indicated, a knowledge of the patient's strengths and resources is important; in short, what qualities does the patient bring to treatment that can enhance the chances of improvement?

## VARYING TYPES OF ASSESSMENT DATA

Because a wide range of factors can play important roles in causing and maintaining maladaptive behavior, assessment may involve the coordinated use of physical, psychological, and environmental assessment procedures. As we have indicated, however, the nature and comprehensiveness of clinical assessments vary depending on the problem and the treatment agency's facilities. Assessment by phone in a suicide prevention center (Stelmachers, 1995), for example, is quite different from assessment aimed at determining whether a hospitalized patient is sufficiently intelligent, verbal, and psychologically minded to be likely to profit significantly from individual psychotherapy.

Furthermore, exactly how a clinician goes about the assessment process often depends on his or her basic orientation. For example, a biologically oriented clinician, typically a psychiatrist or other medical practitioner, will likely focus on biological assessment methods aimed at determining any underlying organic malfunctioning that may be causing the maladaptive behavior. A psychoanalytically oriented clinician may choose unstructured personality assessment techniques, such as the Rorschach inkblots or the Thematic Apperception Test (TAT), to identify latent intrapsychic conflicts. A behaviorally oriented clinician, in an effort to determine the functional relationships between environmental events or reinforcements and the abnormal behavior, will rely on such techniques as behavioral observation and systematic self-monitoring to identify maladaptive learned patterns; for a cognitively oriented behaviorist, the focus would shift to the dysfunctional thoughts supposedly mediating those patterns. A humanistically oriented clinician might use interview techniques to uncover blocked or distorted personal growth, and an interpersonally oriented clinician might use such techniques as personal confrontations and behavioral observations to pinpoint difficulties in interpersonal relationships.

The preceding examples represent general trends and are in no way meant to imply that clinicians of a particular orientation limit themselves to a particular assessment method or that each assessment technique is limited to a particular theoretical orientation. Such trends are instead a matter of emphasis and point up the fact that certain types of assessments are more conducive than others to uncovering particular causal factors, or for eliciting information about symptomatic behavior central to understanding and treating the disorder within a given conceptual framework.

In what follows, we will discuss the way in which both physical and psychosocial data are collected. Then we will examine an actual psychological study that has drawn on a variety of assessment data.

## IMPORTANCE OF RAPPORT BETWEEN THE CLINICIAN AND THE CLIENT

Before psychological assessment can proceed effectively to provide a clear understanding of the patient's behavior and symptoms, good rapport needs to be established between the clinician and the person being evaluated. Important components of a good relationship in a clinical assessment situation include the following:

- Clients need to be feel that the testing will help the practitioner gain a clear understanding of their problems. Clients need to understand how the tests will be used and how the psychologist will incorporate them in the clinical evaluation.
- Individuals being assessed in mental health settings are asked to provide a great deal of personal information. They need to be assured that the feelings, beliefs, attitudes, and personal history that they are disclosing will be appropriately used and will be kept in strict confidence and made available only to therapists or others involved in the case. An important aspect of confidentiality is that the test results are released to a third party only if the client signs an appropriate release form. In cases in which the person is being tested for a third party, such as the court system, the client in effect becomes the referring source—the judge ordering the evaluation—not the individual being tested. In these cases the testing relationship is likely to be strained and rapport is likely to be difficult. Of course, in a court-ordered evaluation the person's test-taking behavior is likely to be very different from what it would be otherwise, and the test interpretation needs to reflect this different motivational set.
- Clients being tested in a clinical situation are usually highly motivated to be evaluated and usually like to know the results of the testing. Moreover, providing test feedback in a clinical setting can be an important element in the treatment process (Beutler, 1995). Interestingly, when patients are given appropriate feedback on the test results they tend to improve—just from gaining a perspective on their problems from the testing. Finn and Tonsager (1992) recently showed that the test feedback process itself can be a powerful clinical intervention. They conducted a clinical study in which one group of patients from a therapy waiting list was provided MMPI-2 test feedback. The second group of patients from the waiting list was administered the MMPI-2 but not given test feedback. The results of the study were informative: They found that persons who were provided feedback on their MMPI-2, compared with the control group, showed a significant decline in reported symptoms and an increase in measured self-esteem.

## ASSESSMENT OF THE PHYSICAL ORGANISM

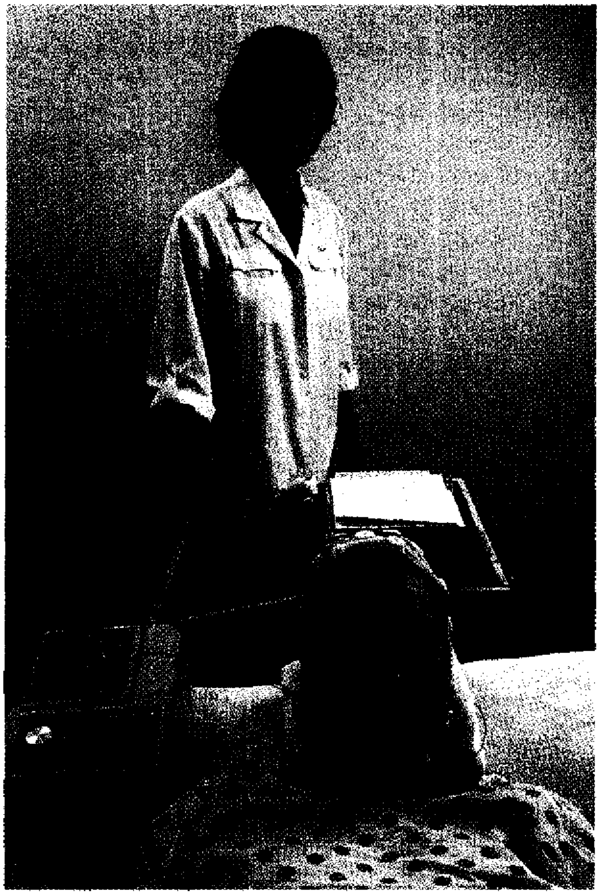
In some situations or with certain psychological problems, a medical evaluation is necessary to rule out physical abnormalities that may be causing or contributing to the problem. The medical evaluation may include both general physical and special examinations aimed at assessing the structural (anatomical) and functional (physiological) integrity of the brain as a behaviorally significant physical system.

## The General Physical Examination

A physical examination consists of the kinds of procedures most of us have experienced in getting a "medical checkup." Typically, a medical history is obtained and the major systems of the body are checked. This part of the assessment procedure is of obvious import for disorders that entail physical problems, such as psychogenically induced disease, and somatoform, addictive, and organic brain syndromes. In addition, a variety of organic conditions, including various hormonal irregularities, can produce in some people behavioral symptoms that closely mimic those of mental disorders usually considered to have predominantly psychosocial origins. A case in point is the problem of chronic back pain in which psychological factors might play an important part. A diagnostic error in this type of situation resulting in surgery that proves ineffective could prove costly; hence, in equivocal cases most clinicians insist on a medical clearance before initiating psychosocially based interventions.

## The Neurological Examination

Because brain pathology is involved in some mental disorders, a specialized neurological examination is frequently given in addition to the general medical examination. This may involve getting an **electroencephalogram (EEG)** to assess brain-wave patterns in awake and sleeping states. An EEG is a graphic record of the brain's electrical activity. It is obtained by placing electrodes on the scalp and amplifying the minute brain-wave impulses from various brain areas; these amplified impulses drive oscillating pens whose deviations are traced on a strip of paper moving at a constant speed. Much is known about the normal pattern of brain impulses in waking and sleeping states and under various conditions of sensory stimulation. Significant divergences from the normal pattern can thus reflect abnormalities of brain function, such as might be caused by a brain tumor or other lesion. When an EEG reveals a **dysrhythmia** in the brain's electrical activity, other specialized techniques may be used in an attempt to arrive at a more precise diagnosis of the problem.

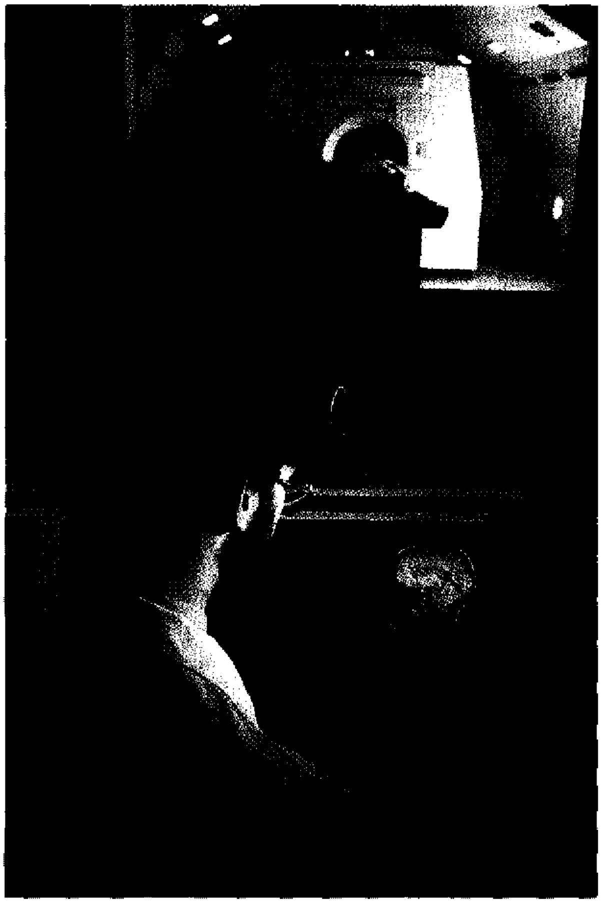


*An electroencephalogram (EEG), a graphic record of the brain's electrical activity, is obtained by placing electrodes on the scalp that pick up brain impulses.*

Radiological technology, such as **computerized axial tomography,** known in brief as the **CAT scan,** is one of these specialized techniques. Through the use of X rays, a CAT scan reveals images of parts of the brain that might be diseased. This procedure has revolutionized neurological study in recent years by providing rapid access, without surgery, to accurate information about the localization and extent of anomalies in the brain's structural characteristics. The procedure involves the use of computer analysis applied to X-ray beams across sections of a patient's brain to produce images that a neurologist can then interpret.

A newer scanning technique is **positron emission tomography,** the **PET scan.** Though a CAT scan is limited to distinguishing anatomical features, such as the shape of a particular internal structure, a PET scan allows for an appraisal of how an organ is functioning by measuring metabolic processes. The PET scan provides metabolic portraits through tracking natural compounds, like glucose, as they are metabolized by the brain or other organs. By revealing areas of differential metabolic activity, the PET scan enables a medical specialist to obtain more clear-cut diagnoses of brain pathology by, for example, pinpointing sites responsible for epileptic seizures, trauma from head injury or stroke, and brain tumors. Thus the PET scan may be able to reveal problems that are not immediately apparent anatomically. Moreover, the use of PET scans in research on brain pathology occurring in abnormal conditions, such as schizophrenia, depression, and alcoholism has the potential of leading to important discoveries about the organic processes underlying these disorders, thus providing clues to more effective treatment. To date, unfortunately, progress on this front has not, in our judgment, proved very illuminating.

The newest of these internal scanning techniques is **nuclear magnetic resonance imaging (MRI).** Like a CAT scan, this procedure allows visualization of the anatomical features of internal organs, including the brain. Unlike a CAT scan, protracted X-ray of the site of interest is not required, and yet the images obtained are often decidedly clearer. Essentially, MRI involves the precise measurement of variations in magnetic fields that are caused by the varying amounts of water content of various organs and parts of organs. In this manner the anatomical structure of a cross section at any given plane through an organ such as the brain can be computed and graphically depicted with astonishing structural differentiation and clarity. MRI thus makes possible, by noninvasive means, visualization of all but the most minute abnormalities of brain structure. It has been particularly useful in confirming degenerative brain processes, as manifested, for example, in enlarged cerebrospinal fluid spaces within the brain. Therefore, MRI studies have considerable potential to illuminate the contribution of brain anomalies to "nonorganic" psychoses, such as schizophrenia, and some progress in this area has in fact been made, as noted in Chapter 12.



*Nuclear magnetic resonance imaging (MRI) allows visualization of the anatomical features of the brain without protracted X-raying, as in CAT scans. In MRI an anatomical structure can be computed and graphically depicted with astonishing differentiation and clarity.*

## The Neuropsychological Examination

The techniques so far described are fairly accurate in identifying abnormalities in the brain's physical properties. Usually, although by no means always, such abnormalities are accompanied by gross impairments in behavior and varied psychological deficits, although the nature of the latter may not be accurately predicted even after precisely localizing these physical abnormalities. Also, behavioral and psychological impairments due to organic brain abnormalities may become manifest before any organic brain lesion is detectable by scanning or other means. In these instances reliable techniques are needed to measure any alteration in behavioral or psychological functioning that has occurred because of the organic brain pathology. This need is met by a growing cadre of psychologists specializing in **neuropsychological assessment,** which involves the use of an expanding array of testing devices to measure a person's cognitive, perceptual, and motor performance as clues to the extent and location of brain damage.

In many instances of known or suspected organic brain involvement, a clinical neuropsychologist will administer a test battery to a patient. The person's performance on standardized tasks, particularly perceptual-motor ones, can give valuable clues about any cognitive and intellectual impairment following brain damage (Filskov & Locklear, 1982; Miller, 1992; Reitan & Wolfson, 1985). Such testing can even provide clues as to the probable location of the brain damage, though PET scans, MRIs, and other

15.1

## Neuropsychological Examinations: Determining Brain-Behavior Relationships

The Halstead-Reitan battery is a neuropsychological examination composed of several tests and variables from which an "index of impairment" can be computed (Reitan & Wolfson, 1985). In addition, it provides specific information about a subject's functioning in several skill areas. Though it typically takes 4–6 hours to complete and requires substantial administrative time, it is being used increasingly in neurological evaluations because it yields a great deal of useful information about an individual's cognitive and motor processes (Filskov & Boll, 1986; Filskov & Goldstein, 1974; Filskov & Locklear, 1982). The Halstead-Reitan battery for adults is made up of the following tests:

1. *The Halstead Category Test* measures a subject's ability to learn and remember material and can provide clues as to his or her judgment and impulsivity. The subject is presented with a stimulus (on a screen) that suggests a number between 1 and 4. The subject presses a button indicating which number is "correct." A correct choice is followed by the sound of a pleasant doorbell and an incorrect choice by a loud buzzer. The person is required to determine from the pattern of buzzers and bells what the underlying principle of the correct choice is.

2. *The Tactual Performance Test* measures a subject's motor speed, response to the unfamiliar, and ability to learn and use tactile and kinesthetic cues. The test consists of a board that has spaces for ten blocks of varied shapes. The subject is blindfolded (never actually seeing the board) and asked to place the blocks into the correct grooves in the board. Later, the subject is asked to draw the blocks and the board from tactile memory.

3. *The Rhythm Test* is an auditory perception task used to measure attention and sustained concentration. It is a subtest of Seashore's Test of musical talent and includes 30 pairs of rhythmic beats that are presented on a tape recorder. On this test, a subject is required to determine if the pairs are the same or different.

4. *The Speech Sounds Perception Test* is a test to determine if an individual can identify spoken words. Nonsense words are presented on a tape recorder, and the subject is asked to identify the presented word from a list of four printed words. This task measures the subject's concentration, attention, and comprehension.

5. *The Finger Oscillation Task* measures the speed at which an individual can depress a lever with the index finger. Several trials are given with each hand.

In addition to the Halstead-Reitan battery, other tests, referred to as allied procedures, may be used in a neuropsychology laboratory. For example, Boll (1980) recommends the use of the modified Halstead-Wepman Aphasia Screening Test for obtaining information about a subject's language ability and about his or her abilities to identify numbers and body parts, to follow directions, to spell, and to pantomime simple actions.

physical tests are more effective in determining the exact location of the injury.

Many neuropsychologists prefer to select a highly individualized array of tests to administer, depending on a patient's case history and other available information. Others opt for a battery consisting of a standard set of tests that have been preselected so as to sample in a systematic and comprehensive manner a broad range of psychological competencies known to be adversely affected by various types of brain injury. The use of a constant set of tests has many research and clinical advantages, although it may compromise flexibility. One such standard battery, widely used, is the Halstead-Reitan, whose components are described in HIGHLIGHT 15.1.

Typically taking about six hours to administer, the Halstead-Reitan can be a problem in some clinical settings where time and funding are limited. Understandably, examinee fatigue may also be a limiting factor, particularly where a patient is not well. Another neuropsychological battery, the Luria-Nebraska (Golden, 1978), which takes only about two and a half hours to administer, has received much attention as an alternative to the Halstead-Reitan. Both these batteries, as well as others of similar purpose and construction, provide their information without the risks attendant to more invasive neurological examination procedures (Filskov & Goldstein, 1974). Still, however, the Halstead-Reitan battery continues to grow in use because it yields a great deal of useful information—more than the Luria-Nebraska—about a patient's cognitive and motor processes (Boll, 1980; Filskov & Locklear, 1982; Hartlage, Asken, & Hornsby, 1987).

In summary, the medical and neuropsychological sciences are developing many new procedures to assess brain functioning and behavioral manifestations of organic disorder. Medical procedures to assess organic brain damage include EEGs and CAT, PET, and MRI scans. The new technology holds a great deal of promise for detecting and evaluating organic brain dysfunction and for providing increased understanding of brain functioning through graphic mapping of the brain. Neuropsychological testing provides a clinician with important behavioral information on how organic brain damage is affecting a person's present functioning.

## PSYCHOSOCIAL ASSESSMENT

Psychosocial assessment attempts to provide a realistic picture of an individual in interaction with the environment. This picture includes relevant information concerning the individual's personality makeup and present level of functioning, as well as information about the stressors and resources in his or her life situation. For example, early in the process, clinicians may act like puzzle solvers, absorbing as much information about the client as possible—present feelings, attitudes, memories, demographic facts, and so on—and trying to fit the pieces together into a meaningful pattern. They typically formulate hypotheses and discard or confirm them as they proceed. Starting with a global technique, such as a clinical interview, clinicians may later select more specific assessment tasks or tests. The following are some of the psychosocial procedures that may be used.

### Assessment Interviews

An assessment interview, often considered the central element of the assessment process, usually involves a face-to-face interaction in which a clinician obtains information about various aspects of a patient's situation, behavior, and personality makeup. The interview may vary from a simple set of questions or prompts, as in the *mental status exam* used chiefly by psychiatrists and other physicians, to a more extended and detailed format. It may be relatively open in character, with an interviewer making moment-to-moment decisions about his or her next question based on responses to prior ones, or it may be more tightly controlled and structured so as to ensure that a particular set of questions is introduced. In the latter case, the interviewer may choose from a number of highly structured, standardized interview formats whose reliability has been established in prior research. As used here, ***reliability*** means simply that two interviewers assessing the same client will generate highly similar conclusions about the client, a type of consensus that research shows can by no means be taken for granted.

Although we know of few clinicians who express enthusiasm for the more controlled and structured type of assessment interview, the research data are clear in showing it to yield far more reliable results, in general, than the more flexible format. There appears to be widespread overconfidence among clinicians in the accuracy of their own methods and judgments (Garb, 1989; Kleinmuntz, 1990). On the other hand, every rule has its exceptions, and we have seen brilliantly conducted assessment interviews where each question was fashioned on the spur of the moment. In most instances, however, an assessor would be wise to conduct an interview that is carefully structured in terms of goals, comprehensive symptom review, other content to be explored, and the type of relationship the interviewer attempts to establish with the subject. Such an approach is likely to minimize error over the long term, although we acknowledge that a more creative and spontaneous interview format may be more productive in particular clinical situations.

The reliability of the assessment interview may also be enhanced by the use of rating scales that help focus inquiry and quantify the interview data. For example, a subject may be rated on a three-, five-, or seven-point scale with respect to self-esteem, anxiety, and various other characteristics. Such a structured and preselected format is particularly effective in giving a comprehensive impression or "profile" of the subject and his or her life situation, and in revealing specific problems or crises—such as marital difficulties, drug dependence, or suicidal fantasies—that may require immediate therapeutic intervention.

As already suggested, clinical interviews are subject to error and have been criticized as an unreliable source of information on which to base important clinical decisions. Evidence of this unreliability includes the fact that different clinicians have often arrived at different formal diagnoses based on interview data they elicit for a particular patient. It is chiefly for this reason that recent versions of the DSM (that is, III, III-R, and IV) have emphasized an "operational" assessment approach, one that specifies observable criteria for diagnosis and provides specific guidelines for making diagnostic judgments. A clinician who is seeking to render a formal diagnosis thus must incorporate at least minimal structure into the interview or risk missing data essential to such a diagnosis. "Winging it" has limited use in this type of assessment process. Although the available data on the improved reliability of psychiatric diagnoses have shown the operational approach to have decided advantages, there has also doubtless been some cost in reducing interviewer flexibility and in encouraging undue preoccupation with observable "signs" at the expense of overall understanding of patient functioning (Simons, 1987).

As was suggested in Chapter 1, the developments just described can be characterized as favoring the removal of the diagnostician, as a subjective judge, from the diagnostic process; to the degree possible, diagnosis is rendered "automatic." But if a human judge is unnecessary—perhaps even a troublesome source of error—then why not take the further step of computerizing the diagnostic process? Computers, after all, are superb at remembering and following explicitly stated rules for decision making. Where clinically feasible, they can even be used online to ask the same sorts of questions, and elicit the same sorts of answers, as would a human interviewer; that is, a patient can be "interviewed" by a computer terminal or console.

In fact, efforts of this sort have already been developed (Erdman, Klein, & Greist, 1985). Computer programs with highly sophisticated branching subroutines are available to "tailor-make" a diagnostic interview for a patient. Stein (1987), for example, described a program called the Computerized Diagnostic Interview for Children that can conduct a standard psychiatric interview. Several more specific clinical assessment tasks have been adapted for computer administration. For example, Fowler and colleagues (1987) have designed a Clinical Problem Checklist that can provide a therapist with an overview of a client's presenting symptoms. Allen and Skinner (1987) have designed a computer program that takes down a client's alcohol- and drug-abuse history, and Giannetti (1987) has a computer program that records a client's social history. All these programs are fairly easy to administer and can provide a clinician with a wealth of reliable and useful data. A computer-based diagnostic interview program for DSM-IV that can be quite valuable to the clinician conducting a diagnostic evaluation has been published. (see HIGHLIGHT 15.2).

Despite the progress made in reducing subjective factors by computerizing or otherwise making various aspects of the assessment process relatively automatic, it is important to understand that excessive reliance on such techniques can introduce error. The complexity of human behavior is bound to produce many exceptions to any rule. In the final analysis, therefore, there is probably no adequate substitute for expert clinical judgment (Carson, 1990b). Where such judgment is available when needed, these techniques can substantially improve assessment efficiency.

## The Clinical Observation of Behavior

Direct observation of an individual's characteristic behavior has long been considered important for adequate psychosocial assessment. The main purpose of direct observation is to learn more about the person's psychological functioning through the objective description of appearance and behavior in various contexts. Though such observations would ideally occur within the person's natural environment, they are typically confined to clinic or hospital settings. For example, a brief description is usually made of a subject's behavior on hospital admission, and more detailed observations are made periodically on the ward. These descriptions include information about the subject's personal hygiene, emotional behavior, delusions or hallucinations, anxiety, sexual behavior, aggressive or suicidal tendencies, and so on.

In addition to making their own observations, many clinicians enlist their patients' help by providing instruction in self-observation and objective reporting of behavior, thoughts, and feelings as they occur in various natural settings. Such **self-monitoring** can be a valuable aid in determining the kinds of situations, possibly previously unrecognized, in which maladaptive behavior is likely to be evoked, and numerous studies also show it to have therapeutic benefits in its own right. Alternatively, a patient may be asked to fill out a more or less formal self-report or a checklist concerning problematic reactions experienced in various situations. Many instruments have been published in the professional literature and are commercially available to clinicians. These approaches recognize that people are excellent sources of information about themselves. Assuming that the right questions are asked and that people are willing to disclose information about themselves, the results can have a crucial bearing on treatment planning—for example, by providing essential information for structuring a behavioral treatment intervention.

As in the case of interviews, the use of **rating scales** in clinical observation and in self-reports helps not only to organize information but also to encourage reliability and objectivity. That is, the formal structure of a scale is likely to keep unwarranted observer inferences to a minimum. Rating scales

## Clinical Diagnosis by Electronic Computer: The D-Tree

The process of clinical diagnosis can be a complicated and difficult one at times. The current clinical diagnosis system, DSM-IV, contains a number of explicit rules for each diagnostic category that define the symptoms and behavior that the patient must show to meet the particular diagnosis. The diagnostic system was developed in such a way that if the diagnostic criteria are explicitly followed the appropriate diagnostic "match" will be reliably made. One difficulty, of course, is that there are many different diagnostic categories with similar exclusion and inclusion rules. Therefore, the clinician needs to approach the classification task in a highly systematic manner, for example, following a branching strategy until the appropriate diagnostic classification is reached. The recommended diagnostic process follows a "decision tree" approach. Such an approach allows the practitioner to follow the hierarchial structure of DSM-IV and ask the appropriate questions for each diagnostic question until the most appropriate category is reached.

A decision tree begins with a set of particular clinical features. "When one of these features is a prominent part of the presenting clinical picture, the clinician can follow the series of questions to rule in or out various disorders" (American Psychiatric Association, 1994). Several standard decision trees are provided in DSM-IV, for example, a decision tree to develop a differential diagnosis of mental disorders due to a general medical condition and a decision tree to differentially diagnose psychotic disorders. The decision tree approach to classification is illustrated below. The clinician follows the logical flow chart and determines the presence or absence of the criteria for the patient in question. The following decision tree for somatoform disorders from DSM-IV illustrates this approach on the next page.

The branching strategy for the decision tree presents the clinician with a sequence of specific diagnostic questions such as "are hallucinations present," to which "yes" or "no" responses determine the appropriate next question until a particular diagnosis is confirmed. Given the fact that a clinician can be presented with all of the appropriate questions in a systematic manner, this decision sequence could be asked and recorded in a very automatic, systematic way by a computer. The diagnostic process, in terms of the appropriate sequence of questions to address, has been demonstrated to be effectively accomplished by computer. Michael First, a noted psychiatrist who has a substantial background and education in computer programming, wrote a diagnostic program for DSM-III-R that came to be widely used by psychiatrists for both clinical assessment and training. He has recently revised this computer program, the D-Tree (Multi Health Systems, 1995) to provide DSM-IV diagnoses.

The D-Tree computer software is designed to guide the practitioner through the diagnostic process by presenting appropriate questions to the clinician. When all relevant information is provided, the computer gives the most likely DSM-IV diagnosis. If the clinician fails to provide the needed information in response to a question, the program halts and an instruction urges the clinician to seek the needed information. If, for example, the D-Tree program requests information about whether the patient has had auditory hallucinations and the practitioner has failed to assess this area, then he or she might reinterview the patient to obtain the needed data.

The D-Tree program has been a highly successful means of providing reliable clinical diagnoses as well as serving as a training guide for DSM-IV. Practitioners who use this computer aid soon become aware of the explicit rules to follow in developing DSM-IV diagnoses and the need to obtain clear verification of all the elements of a diagnosis before conclusions are reached about the patient.

---

commonly used are those that enable a rater to indicate not only the presence or absence of a trait or behavior but also its prominence. The following is an example of such a rating-scale item; the observer would check the most appropriate alternative.

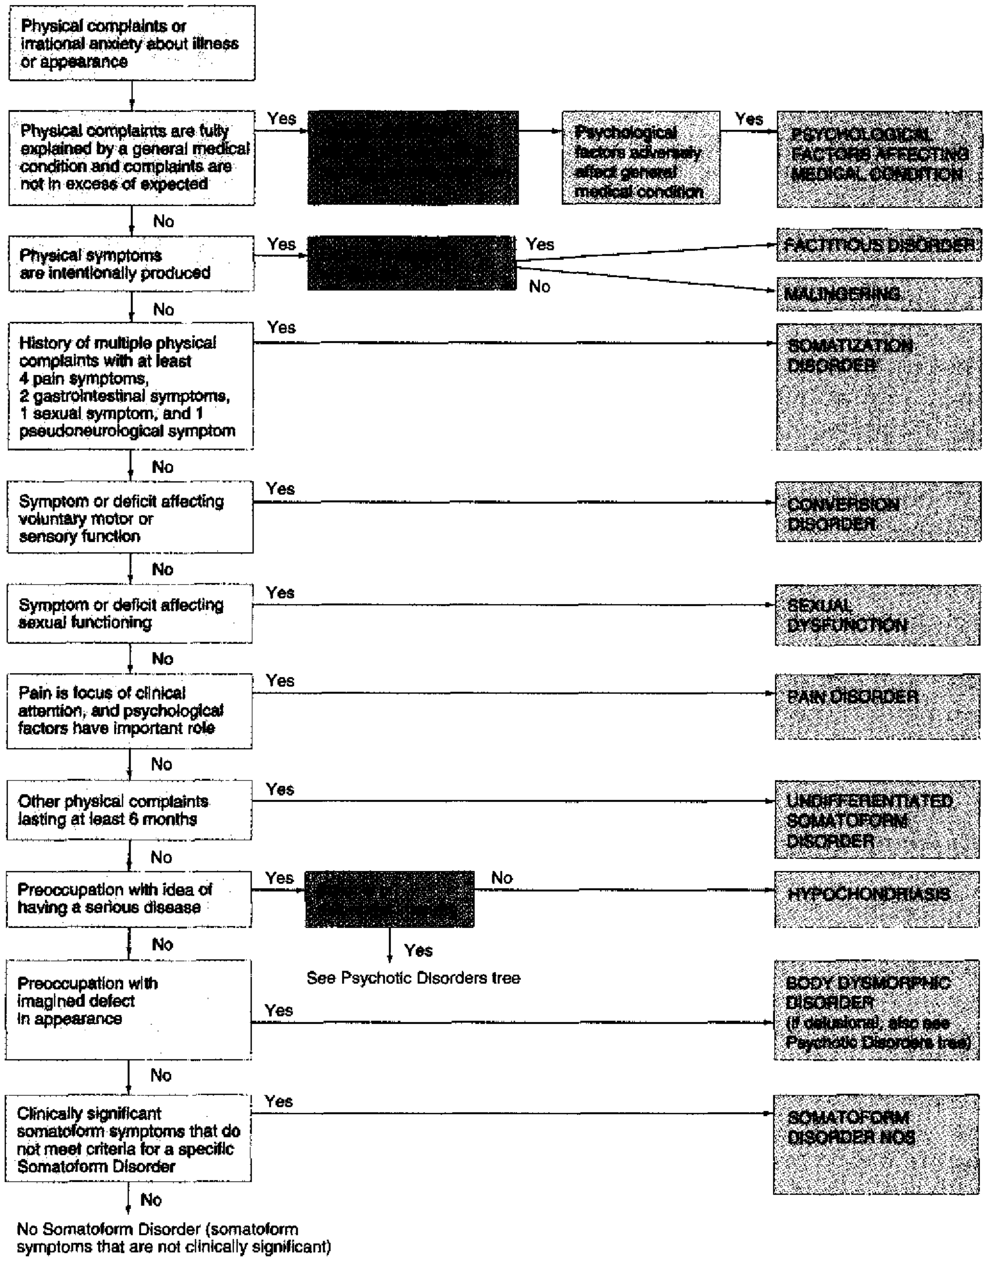
*Sexual behavior:*

____1. Sexually assaultive: aggressively approaches males or females with sexual intent.

____2. Sexually soliciting: exposes genitals with sexual intent, makes overt sexual advances to other patients or staff, masturbates openly.

____3. No overt sexual behavior: not preoccupied with discussion or sexual matters.

____4. Avoids sex topics: made uneasy by discussion of sex, becomes disturbed if approached sexually by others.



Physical complaints or irrational anxiety about illness or appearance
Physical complaints are fully explained by a general medical condition and complaints are not in excess of expected
Yes
Psychological factors adversely affect general medical condition
Yes
PSYCHOLOGICAL FACTORS AFFECTING MEDICAL CONDITION
No
Physical symptoms are intentionally produced
Yes
Yes
FACTITIOUS DISORDER
No
MALINGERING
No
History of multiple physical complaints with at least 4 pain symptoms, 2 gastrointestinal symptoms, 1 sexual symptom, and 1 pseudoneurological symptom
Yes
SOMATIZATION DISORDER
No
Symptom or deficit affecting voluntary motor or sensory function
Yes
CONVERSION DISORDER
No
Symptom or deficit affecting sexual functioning
Yes
SEXUAL DYSFUNCTION
No
Pain is focus of clinical attention, and psychological factors have important role
Yes
PAIN DISORDER
No
Other physical complaints lasting at least 6 months
Yes
UNDIFFERENTIATED SOMATOFORM DISORDER
No
Preoccupation with idea of having a serious disease
Yes
No
HYPOCHONDRIASIS
Yes
See Psychotic Disorders tree
No
Preoccupation with imagined defect in appearance
Yes
BODY DYSMORPHIC DISORDER (if delusional, also see Psychotic Disorders tree)
No
Clinically significant somatoform symptoms that do not meet criteria for a specific Somatoform Disorder
Yes
SOMATOFORM DISORDER NOS
No
No Somatoform Disorder (somatoform symptoms that are not clinically significant)

____5. Excessive prudishness about sex: considers sex filthy, condemns sexual behavior in others, becomes panic-stricken if approached sexually.

Ratings like these may be made not only as part of an initial evaluation but also to check on the course or outcome of treatment.

One of the rating scales most widely used for recording observations in clinical practice and in psychiatric research is the *Brief Psychiatric Rating Scale (BPRS)*. The BPRS provides a structured and quantifiable format for rating clinical symptoms, such as somatic concern, anxiety, emotional withdrawal, guilt feelings, hostility, suspiciousness, and unusual thought patterns. It contains 18 scales that are scored from ratings made by a clinician following an interview with a patient. The distinct patterns of behavior reflected in the BPRS ratings enable clinicians to make a standardized comparison of their patients' symptoms with the behavior of other psychiatric patients (Overall & Hollister, 1982). The BPRS has been found to be an extremely useful instrument in clinical research, especially for the purpose of assigning patients to treatment groups on the basis of similarity in symptoms. A similar but more specifically targeted instrument, the *Hamilton Rating Scale for Depression (HRSD)*, has become almost the standard in this respect for selecting clinically depressed research subjects, and also for assessing the response of such subjects to various treatments.

Observations made in clinical settings by trained observers can provide behavioral data useful in ongoing clinical management. Paul and colleagues (Mariotto, Paul, & Licht, 1995; Paul & Lentz, 1977; Rich, Paul, & Mariotto, 1988), for example, have developed a comprehensive behavioral assessment program that they have implemented experimentally in a number of hospitals. The program includes evaluating the behavior of chronic patients and monitoring the activities of staff members working with them. Through the use of observational rating systems, they have been able to measure staff behavior in the daily management of patients and ongoing patient behavior on the ward. The behavioral ratings can be used to pinpoint specific behaviors to be changed on the part of members of either group.

Recently, a good deal of attention has focused on observing a subject's behavior in his or her natural surroundings (Leichtman, 1995). For example, children with behavior problems may be observed at home, at school, and in their peer groups. Here the purpose is to obtain a sampling of their behavior in ordinary situations to understand the problems they are facing, the coping patterns they are using, and the environmental conditions that may be reinforcing their maladaptive behavior.

The procedures described above focus on a subject's overt behavior, omitting the often equally important consideration of concurrent mental events—that is, the individual's ongoing thoughts. In an attempt to sample naturally occurring thoughts, psychologists are experimenting with having individuals carry small electronic beepers that produce a signal, such as a soft tone, at unexpected intervals. At each signal, the person is to write down or electronically record whatever thoughts the signal interrupted. These "thought reports" can then be analyzed in various ways, and can be used for some kinds of personality assessment and diagnosis as well as for monitoring progress in psychological therapy (Klinger & Kroll-Mensing, 1995).

*It can be helpful to both a practitioner and a client to observe and assess the client's behavior in an everyday setting, such as his or her home, where there is the opportunity to talk with family members and to discern the stressors and resources in the client's life situation.*

In situations where it is not feasible to observe a subject's behavior in everyday settings—as when he or she is institutionalized—an entire family may be asked to meet together in the clinic or hospital where their interactions and difficulties can be observed and studied. In other cases, a social worker may obtain relevant data by visiting a subject's home, talking with family members and others, and observing the stressors and resources in the subject's life situation. In addition to providing important assessment data, this procedure incorporates the "observers" into the therapy program, thereby enhancing the therapy.

Where the object of study is a child, Jones, Reid, and Patterson (1975) have developed a method for coding and quantifying the observations of the child's behavior at school and at home. Concrete instances of behavior and interaction can be observed, recorded, and coded, either by trained observers or by the parents themselves. This method provides the clinician with information about the stimuli that are controlling the child's interactions, which in turn makes it possible for the clinician to evaluate the quality of the child's interactions and to identify the situations that result in behavior problems.

In still other situations where observation in a natural setting is not possible, a clinician may construct or contrive observational opportunities that can provide information about a person's response to particular circumstances. For example, a person who has a phobia for snakes might be placed in a situation where snakelike objects and pictures are presented.

An often-used procedure that enables a clinician to observe a client's behavior directly is **role playing.** The client is instructed to play a part—for example, someone standing up for his or her rights. Role playing a situation like this not only can provide assessment information for the clinician but also can serve as a vehicle for new learning for the client.

## Psychological Tests

Interviews and behavioral observation are relatively direct attempts to determine a person's beliefs, attitudes, and problems. Psychological tests, on the other hand, are a more indirect means of assessing psychological characteristics. Scientifically developed psychological tests (as opposed to the recreational ones sometimes appearing in newspapers and magazines) are standardized sets of procedures or tasks for obtaining samples of behavior; a subject's responses to the standardized stimuli are compared with those of other people having comparable demographic characteristics, usually through established test norms or test score distributions. From these comparisons, a clinician can then draw inferences about how much the person's psychological qualities differ from those of a reference group, typically a psychologically normal one. Among the characteristics these tests can measure are coping patterns, motive patterns, personality characteristics, role behaviors, values, levels of depression or anxiety, and intellectual functioning. Impressive advances in the technology of test development have in fact made it possible to develop instruments of acceptable reliability and validity to measure almost any conceivable psychological characteristic in which people vary.

Though more precise and often more reliable than interviews or less standardized observational techniques, psychological tests are far from perfect tools. Their value often depends on the competence of the clinician who interprets them (Carson, 1990b). In general, they are useful diagnostic tools for psychologists in much the same way that blood tests, X-ray films, or MRI scans are useful to physicians. In all these cases, pathology may be revealed in people who appear to be normal, or a general impression of "something wrong" can be checked against more precise information.

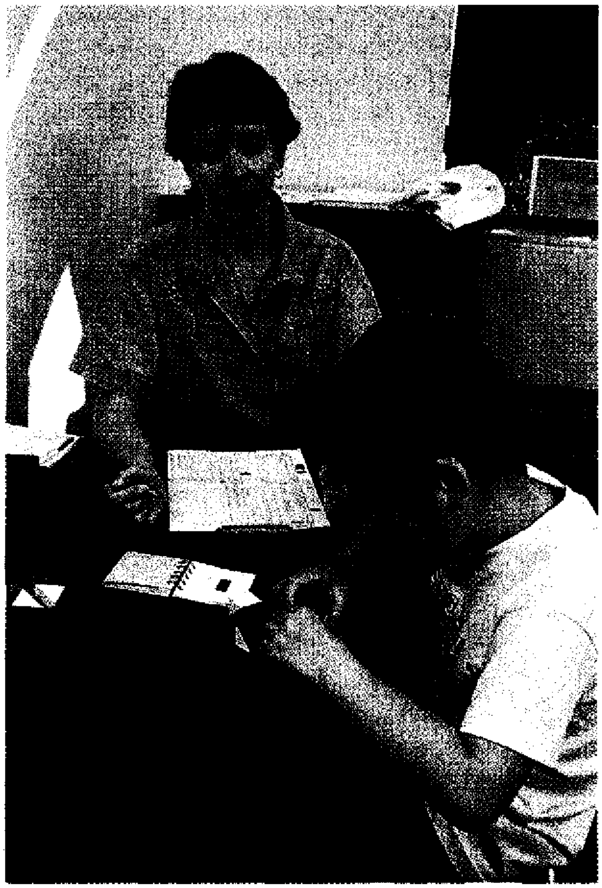
Two general categories of psychological tests for use in clinical practice are *intelligence tests* and *personality tests.* We discuss each in the following sections.

**Intelligence Tests** A clinician can choose from a wide range of intelligence tests. The Wechsler Intelligence Scale for Children-Revised (WISC-R) and the current edition of the Stanford-Binet Intelligence Scale are widely used in clinical settings for measuring the intellectual abilities of children. Probably the most commonly used test for measuring adult intelligence is the Wechsler Adult Intelligence Scale-Revised (WAIS-R). It includes both verbal and performance material and consists of 11 subtests. A brief description of two of the subtests—one verbal and one performance—will serve to illustrate the type of functions the WAIS-R measures:

> General information (verbal). This subtest consists of questions designed to evaluate the individual's range of information on material that is ordinarily encountered. For example, the individual is asked to do such things as tell how many weeks there are in a year, name the colors of the American flag, and tell who Martin Luther King was.
>
> Picture completion (performance). This subtest consists of 20 cards showing pictures, each with a part missing; the subject's task is to indicate what is missing. This test is designed to measure the individual's ability to discriminate between essential and nonessential elements in a situation. (Wechsler, 1981)

Individually administered intelligence tests—such as the WISC-R, WAIS-R, and the Stanford-Binet—typically require 2–3 hours to administer, score, and interpret. In many clinical situations, there is not sufficient time or funding to use these tests in every assessment situation. In cases where intellectual impairment or organic brain damage is thought to be central to a patient's problem, intelligence testing may be the most crucial diagnostic procedure to include in the test battery. Moreover, information about the cognitive functioning of patients can provide valuable clues as to the person's intellectual resources in dealing with problems (Zetzer & Beutler, 1995). Yet in many clinical settings and for many clinical cases, gaining a thorough understanding of a client's problems and initiating a treatment program do not require knowing the kind of detailed information about intellectual functioning these instruments provide. In these cases, intelligence testing would not be recommended.

**Personality Tests** There are a great many tests designed to measure personal characteristics other than intellectual facility. It is customary to group



*A psychologist administering the WISC, an intelligence test that provides information about how well a child performs on a variety of cognitive challenges. An individually administered test such as this can require considerable time—often 2–3 hours—to give, score, and interpret; as such, it is appropriate to use these types of tests primarily when intelligence testing is considered critical to the diagnosis.*

these personality tests into ***projective*** and ***objective*** tests.

*Projective Tests.* **Projective tests** are unstructured in that they rely on various ambiguous stimuli, such as inkblots or pictures, rather than explicit verbal questions, and subjects' responses are not limited to the "true," "false," or "cannot say" variety. Through their interpretations of these ambiguous materials, subjects reveal a good deal about their personal preoccupations, conflicts, motives, coping techniques, and other personality characteristics. An assumption underlying the use of projective techniques is that in trying to make sense out of vague, unstructured stimuli, individuals "project" their own problems, motives, and wishes into the situation, inasmuch as they have little else on which to rely in formulating their responses to these materials (Lerner, 1995). Such responses are akin to the childhood pastime of detecting familiar scenes in cloud formations, with the important exception that the stimuli are in this case fixed and largely the same for all subjects. It is the latter circumstance that permits determination of the normative range of responses to the test materials, which in turn can be used to identify objectively deviant responding. Thus projective tests are aimed at discovering the ways in which an individual's past learning and personality structure may lead him or her to organize and perceive ambiguous information from the environment. Prominent among the several projective tests in common use are the Rorschach Test, the Thematic Apperception Test (TAT), and sentence-completion tests.

The **Rorschach Test** is named after the Swiss psychiatrist Hermann Rorschach, who initiated experimental use of inkblots in personality assessment in 1911. The test uses ten inkblot pictures to which a subject responds in succession after being instructed somewhat as follows (Exner, 1993):

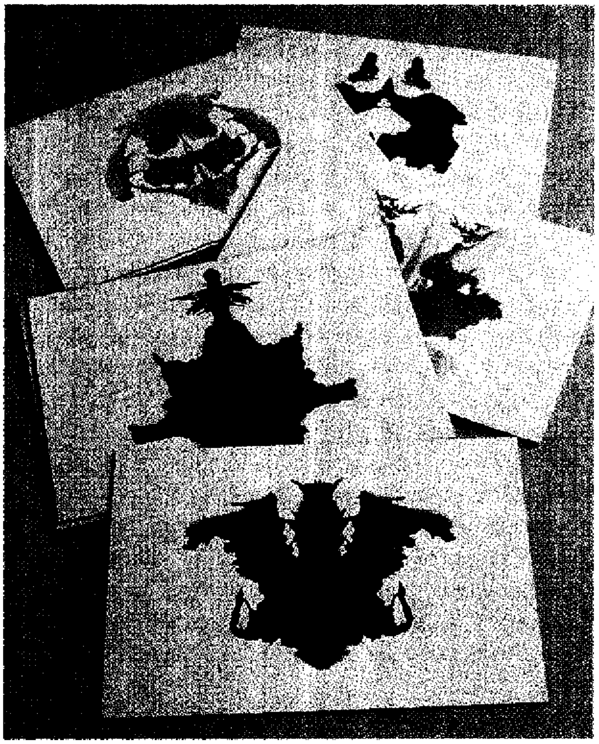
> People may see many different things in these inkblot pictures; now tell me what you see, what it makes you think of, what it means to you.

The following excerpts are taken from the responses of a subject to one of the actual blots:

> "This looks like two men with genital organs exposed. They have had a terrible fight and blood has splashed up against the wall. They have knives or sharp instruments in their hands and have just cut up a body. They have already taken out the lungs and other organs. The body is dismembered . . . nothing remains but a shell . . . the pelvic region. They were fighting as to who will complete the final dismemberment . . . like two vultures swooping down. . . ."

The extremely gory, violent content of this response was not common for the particular blot, nor for any other blot in the series. While no responsible examiner would base conclusions on a single instance, such content was consistent with other data from this subject, who was diagnosed as an antisocial personality with strong hostility.

Use of the Rorschach in clinical assessment is complicated and requires considerable training (Exner, 1991; Exner & Weiner, 1994). Methods of administering the test vary, and some approaches can take several hours and hence must compete for time with other essential clinical services. Furthermore, the results of the Rorschach can be unreliable



*The Rorschach Inkblot Test, which uses blots similar to those illustrated here, is a well-known projective test.*

because of the subjective nature of test data interpretations. In addition, the types of clinical treatments used in most of today's mental health facilities generally require specific behavioral descriptions rather than descriptions of deep-seated personality dynamics, such as those that typically result from Rorschach Test interpretation.

The Rorschach has been criticized, to some extent unfairly, as an instrument with low or negligible validity. In the hands of a skilled interpreter, the Rorschach has been shown to be useful in uncovering certain psychodynamic issues, such as the impact of unconscious motivations on current perceptions of others. Furthermore, there have been attempts to move beyond the original discursive and free-wheeling approaches and to objectify Rorschach interpretations by clearly specifying test variables and empirically exploring their relationship to external criteria, such as clinical diagnosis (Exner, 1995).

The Rorschach, although generally considered an open-ended, subjective instrument aimed at studying a person's personality as a uniquely organized system ("idiographically"), has recently been adapted for computer interpretation. Exner (1987) has developed a computer-based interpretation system for the Rorschach that, after scored responses are input, provides scoring summaries and a listing of likely personality descriptions and references about a person's adjustment. The Exner Comprehensive Rorschach System (an example of which can be found in the case study of Esteban in HIGHLIGHT 15.4 on pages 586–588) may answer the criticism that Rorschach interpretation is unreliable, because the computer output provides a reliable and invariant set of descriptors for any given set of Rorschach scores. Assuming that clinicians agree on the scoring of particular responses, the computer outputs, that is, the interpretations, will be the same. Butcher and Rouse (in press) recently reviewed the clinical assessment research literature over the past 20 years including the major clinical assessment methods and found that the Rorschach was the second most frequently researched clinical instrument, the MMPI/MMPI-2 being first. Research studies involving the Rorschach have been fairly steady over the past 20 years with roughly about 80 to 100 articles per year.

The **Thematic Apperception Test (TAT)** was introduced in 1935 by its coauthors, Morgan and Murray of the Harvard Psychological Clinic. It uses a series of simple pictures, some highly representational and others quite abstract, about which a subject is instructed to make up stories. The content of the pictures, much of it depicting people in various contexts, is highly ambiguous as to actions and motives, so that subjects tend to project their own conflicts and worries into it (Bellak & Abrams, 1993).

Several scoring and interpretation systems have been developed to focus on different aspects of a subject's stories, such as expressions of needs (Atkinson, 1992), the person's perception of reality (Arnold, 1962), and the person's fantasies (Klinger, 1979). Generally these systems are time-consuming, and little evidence shows that they make a clinically significant contribution. Hence, most often a clinician simply makes a qualitative and subjective determination of how the story content reflects the person's underlying traits, motives, and preoccupations. Such interpretations often depend as much on "art" as on "science," and there is much room for error in such an informal procedure.

An example of the way a subject's problems may be reflected in TAT stories is shown in the following story based on Card 1 (a picture of a boy staring at a violin on a table in front of him). The client, David, was a 15-year-old boy who had been referred to the clinic by his parents because of their concern about his withdrawal and poor work at school:

> **David was generally cooperative during the testing although he remained rather unemotional and unenthusiastic throughout. When he was**

*The Thematic Apperception Test, or TAT, asks a patient to develop stories about the people depicted in a series of drawings. The patient's stories about the people shown in the cards are thought to reflect personality characteristics, motives, beliefs, attitudes, problems, and symptoms of the person taking the test.*

given Card 1 of the TAT, he paused for over a minute, carefully scrutinizing the card.

"I think this is a . . . uh . . . machine gun . . . yeah, it's a machine gun. The guy is staring at it. Maybe he got it for his birthday or stole it or something." (Pause. The examiner reminded him that he was to make up a story about the picture.)

"OK. This boy, I'll call him Karl, found this machine gun . . . a Browning automatic rifle . . . in his garage. He kept it in his room for protection. One day he decided to take it to school to quiet down the jocks that lord it over everyone. When he walked into the locker hall, he cut loose on the top jock, Amos, and wasted him. Nobody bothered him after that because they knew he kept the BAR in his locker."

It was inferred from this story that David was experiencing a high level of frustration and anger in his life. The extent of this anger was reflected in his perception of the violin in the picture as a machine gun—a potential instrument of violence. The clinician concluded that David was feeling threatened not only by people at school but even in his own home where he needed "protection." This example shows how stories based on TAT cards may provide a clinician with information about a person's conflicts and worries as well as clues as to how the person is handling these problems.

The TAT has been criticized on several grounds in recent years. There is a "dated" quality to the test stimuli: the pictures, developed in the 1930s, appear quaint to many contemporary subjects who have difficulty identifying with the characters in the pictures. Subjects will often preface their stories with, "This is something from a movie I saw on the Late Show." Additionally, the TAT can require a great deal of time to administer and interpret. Interpretation of responses to the TAT is generally subjective and limits the reliability and validity of the test. Again, however, we must note that some examiners, notably those who have long experience in the instrument's use, are capable of astonishingly accurate interpretations with TAT stories. Typically, they have difficulty in teaching these skills to others. On reflection, such an observation should not be unduly surprising, but it does point up the essentially "artistic" element involved at this skill level.

Another projective procedure that has proven useful in personality assessment is the **sentence-completion test.** There are a number of such tests designed for children, adolescents, and adults. Such tests consist of the beginnings of sentences that a subject is asked to complete, as in these examples:

1. I wish ____________________
2. My mother ____________________
3. Sex ____________________
4. I hate ____________________
5. People ____________________

Sentence-completion tests are somewhat more structured than the Rorschach and most other projective tests. They help examiners pinpoint important clues to an individual's problems, attitudes, and symptoms through the content of his or her responses. Interpretation of the item responses, however, is generally subjective and unreliable. Despite the fact that the test stimuli (the sentence stems) are standard, interpretation is usually done in an ad hoc manner and without benefit of norms.

In sum, projective tests have an important place in many clinical settings, particularly those that attempt to obtain a comprehensive picture of a person's psychodynamic functioning and have the necessary trained staff to conduct extensive individual psychological evaluations. The great strengths of projective techniques—their unstructured nature and their focus on the unique aspects of personality—are at the same time their weaknesses because they make interpretation subjective, unreliable, and difficult to validate. Moreover, projective tests typically require a great deal of time to administer and advanced skill to interpret—both scarce quantities in many clinical settings.

*Objective Tests.* **Objective tests** are structured—that is, they typically use questionnaires, self-inventories, or rating scales in which questions or items are carefully phrased and alternative responses are specified as choices. They therefore involve a far more controlled format than projective devices and thus are more amenable to objectively based quantification. One virtue of such quantification is that of precision, which in turn enhances the reliability of test outcomes.

One of the major structured inventories for personality assessment is the **Minnesota Multiphasic Personality Inventory (MMPI)**, now the **MMPI-2** after a recent revision. We focus on it here because in many ways it is the prototype and the standard of this class of instruments.

Several years in development, the MMPI was introduced for general use in 1943 by Hathaway and McKinley; it is today the most widely used personality test for both clinical assessment and psychopathologic research in the United States (Lubin et al., 1984, 1985; Piotrowski & Keller, 1992) and is the assessment instrument most frequently taught in graduate clinical psychology programs (Piotrowski & Zalewski, 1993). Moreover, translated versions of the inventory are widely used internationally. In all, the MMPI has been translated into more than 115 languages, and it is used in over 46 countries (Butcher, 1984). International use of the revised inventory is increasing at a fast rate. Since it was published in 1989, there have been over 25 translations of the MMPI-2 (Butcher, in press).

The original MMPI, a kind of self-report technique, consisted of 550 items covering topics ranging from physical condition and psychological states to moral and social attitudes. Normally, subjects are encouraged to answer all of the items either *true* or *false*. Some sample items follow:

> I sometimes keep on at a thing until others lose their patience with me. T F
>
> Bad words, often terrible words, come into my mind and I cannot get rid of them. T F
>
> I often feel as if things were not real. T F
>
> Someone has it in for me. T F
>
> (Hathaway & McKinley, 1951, p. 28)

The pool of items for the MMPI was originally administered to a large group of normal individuals (affectionately called the "Minnesota normals") and several quite homogeneous groups of patients having particular psychiatric diagnoses. Answers to all the items were then item-analyzed to see which ones differentiated the various groups. On the basis of the findings, ten clinical scales were constructed, each consisting of the items that were answered by one of the patient groups in the direction opposite to the predominant response of the normal group. This rather ingenious method of scorable item selection, known as ***empirical keying***, was original to the MMPI and doubtless accounts for much of the instrument's power. Note that it involves no subjective prejudgment about the "meaning" of a true or false answer to any item; that meaning resides entirely in whether or not the answer is the same as that deviantly given by patients of varying diagnoses. Most examiners do not even review the actual responses made because doing so encourages speculative hypotheses that have a likelihood of being wrong. Should an examinee's pattern of true/false responses closely approximate that of a particular pathological group, it is a reasonable inference that he or she shares other psychiatrically significant characteristics with that group—and may in fact "psychologically" be a member of that group.

Each of these ten "clinical" scales, then, measures tendencies to respond in psychologically deviant ways. Raw scores on these scales are compared with the corresponding scores of the normal population, many of whom did (and do) answer a few items in the critical direction, and the results are plotted on the standard MMPI profile form. By drawing a line connecting the scores for the different scales, a clinician can construct a profile that shows how far from normal a patient's performance is on each of the scales. The *Schizophrenia scale,* for example (and to reiterate the basic strategy), is made up of the items that schizophrenic patients consistently answered in a way that differentiated them from normal individuals. People who score high (relative to norms) on this scale, though not necessarily schizophrenic, often show propensities typical of the schizophrenic population. For instance, high scorers on this scale may be socially inept, withdrawn, and have peculiar thought processes; they may have diminished contact with reality and in severe cases may have delusions and hallucinations.

The MMPI also includes a number of validity scales to detect whether a patient has answered the questions in a straightforward, honest manner. Extreme endorsement of the items on any of these scales may invalidate the test, while lesser endorsements frequently contribute important interpretive insights. In addition to the validity scales and the ten clinical scales, hundreds of "special" scales have been devised, four of which have become so widely used for both clinical and research purposes that they are now listed on the MMPI profile form. There is in principle no limit to the number of additional scales that could be generated from the MMPI item pool and available item norms.

Clinically, the MMPI is used in several ways to evaluate a patient's personality characteristics and clinical problems. Perhaps the most typical use of the MMPI is as a ***diagnostic standard.*** As we have seen, the individual's profile pattern is compared with profiles of known patient groups. If the profile matches a group, information about patients in this group can suggest a broad ***descriptive diagnosis*** for the patient under study. Another approach to MMPI interpretation, ***content interpretation,*** is used to supplement the empirical correlates provided in the just-described approach. Here, a clinician focuses on the content themes in a person's response to the inventory. For example, if an individual endorses an unusually large number of items about fears, a clinician might well conclude that the subject is preoccupied with fear.

The original MMPI, in spite of being the most widely used personality measure, has not been without its critics. Some psychodynamically oriented clinicians felt that the MMPI (like other structured, objective tests) was superficial and did not adequately reflect the complexities of an individual taking the test. Some behaviorally oriented critics, on the other hand, criticized the MMPI, and in fact the entire genre of personality tests, as being too oriented toward measuring unobservable "mentalistic" constructs, such as traits. A more specific criticism was leveled at the datedness of the MMPI, including in particular its anachronistic item pool and narrow, out-of-date norms. The original MMPI dated from the early 1940s, and even though much of the MMPI interpretive research is much more recent, the item pool and the basic scaling of raw response data had remained unchanged. In response to these criticisms, the publisher of the MMPI contracted to underwrite a revision of the instrument. This revised MMPI, designated MMPI-2 for adults, became available for general professional use in mid-1989 (Butcher et al., 1989) and the MMPI-A, for adolescents (Butcher et al., 1992) was published in 1992. Perhaps inevitably, in light of the distinction of its forebear and the strong loyalties to it, some early reservations were expressed. However, the MMPI-2 has now effectively replaced the original instrument and most users now use the revised versions.

We will provide a brief discussion of the changes that have been made to the original instrument. The scales listed on the standard original MMPI-2 profile form are given in HIGHLIGHT 15.3. The most important changes introduced with MMPI-2 were directed at overcoming the deficiencies already noted—namely (a) the outmoded idioms and sometimes prejudicial language of some of the items in the pool; and (b) the outdated and demographically unrepresentative character of the normal standardization sample, most of whose members came from rural parts of Minnesota in the 1930s. A third major alteration, too technical for detailed discussion here, involves the scaling method used to convert raw scale scores to standardized ones having common parameters (that is, means and standard deviations).

Changes made in the original MMPI item pool can be summarized as follows:

- The original item pool was edited and modernized to eliminate expressions that were out of date and to delete objectionable items (about 14 percent of the items required alteration). Additional items were written to address additional problem areas, such as treatment compliance, Type A behavior, suicide, and personality problems. Two separate item pools were established: an adult form and an adolescent form, designated MMPI-A.
- The new adult normative sample for MMPI-2—2600 subjects randomly sampled from seven communities across the United States—is considerably more representative of the American population than was that for the original MMPI. Efforts were made to include representative groups from different racial and ethnic backgrounds, age groups, and social classes.
- The adolescent form of the MMPI (MMPI-A) was standardized on 815 girls and 805 boys who were students in public and private schools in seven regions of the United States. Designed for use with youngsters aged 14 through 18, it contains a number of new scales. Its basic clinical scales, as in the case of MMPI-2, are the same as for the original MMPI.

The MMPI-2 has been validated in several clinical studies to date (Butcher & Graham, 1994). The clinical scales, which have been retained in their original form apart from minimal item deletion or rewording, seem, as expected, to measure the same properties of personality organization and functioning as they always have. A comparable stability of meaning is observed for the standard validity scales (also essentially unchanged), which have been reinforced with three additional scales to detect tendencies to respond untruthfully to some items. The essential psychometric comparability of the main scales of the two adult versions has been empirically demonstrated by Ben-Porath and Butcher (1989). The basic MMPI-2 profile form is reproduced in HIGHLIGHT 15.4 in the case study of Esteban.

Overall, then, the authors of MMPI-2 have retained the central elements of the original instru-

15.3

## The Scales of the MMPI-2

### Validity Scales

| | |
|---|---|
| Cannot say scale (?) | Measures the total number of unanswered items |
| Lie scale (L) | Measures the tendency to claim excessive virtue or to try to present an overall favorable image |
| Infrequency scale (F) | Measures the tendency to falsely claim or exaggerate psychological problems in the first part of the booklet; alternatively, detects random responding |
| Infrequency scale (Fb) | Measures the tendency to falsely claim or exaggerate psychological problems on items toward the end of the booklet |
| Defensiveness scale (K) | Measures the tendency to see oneself in an unrealistically positive way |
| Response Inconsistency scale (VRIN) | Measures the tendency to endorse items in an inconsistent or random manner |
| Response Inconsistency scale (TRIN) | Measures the tendency to endorse items in an inconsistent true or false manner |

### Clinical Scales

| | | |
|---|---|---|
| Scale 1 | Hypochondriasis (Hs) | Measures excessive somatic concern and physical complaints |
| Scale 2 | Depression (D) | Measures symptomatic depression |
| Scale 3 | Hysteria (Hy) | Measures hysteroid personality features such as a "rose-colored glasses" view of the world and the tendency to develop physical problems under stress |
| Scale 4 | Psychopathic deviate (Pd) | Measures antisocial tendencies |
| Scale 5 | Masculinity-femininity (Mf) | Measures gender-role reversal |
| Scale 6 | Paranoia (Pa) | Measures suspicious, paranoid ideation |
| Scale 7 | Psychasthenia (Pt) | Measures anxiety and obsessive, worrying behavior |
| Scale 8 | Schizophrenia (Sc) | Measures peculiarities in thinking, feeling, and social behavior |
| Scale 9 | Hypomania (Ma) | Measures elated mood state and tendencies to yield to impulses |
| Scale 0 | Social introversion (Si) | Measures social anxiety, withdrawal, and overcontrol |

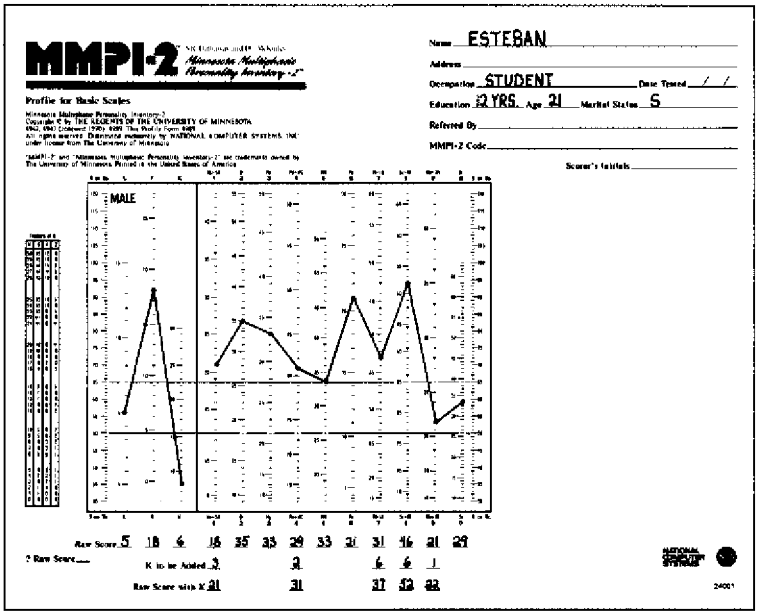
### Special Scales

| | | |
|---|---|---|
| Scale *A* | Anxiety | A factor analytic scale measuring general maladjustment and anxiety |
| Scale *R* | Repression | A factor analytic scale measuring overcontrol and neurotic defensiveness |
| Scale *Es* | Ego strength | An empirical scale measuring potential response to short-term psychotherapy |
| Scale *Mac* | MacAndrew Revised Addiction Scale (MAC-R) | An empirical scale measuring proneness to become addicted to various substances |

ment but have added a number of features and refinements to it, including provision for systematic "content" profile analysis. As was the authors' intent, the scales of MMPI-2 correlate highly with those of the original MMPI. Some interpretive adjustments need to be made with respect to relative scale elevations, however, because the new normative base may have slightly altered the meaning to be assigned to interscale relationships. Experience with the new version to date indicates that practitioners are able, with little change in their interpretive approaches, to use it in the same way they did the original instrument. Recent research (Hargrave et al., 1994; Morrison, Edwards, & Weissman, 1994; and

15.4

## Esteban's MMPI-2 Profile and MMPI-2 Computer-Based Report



Esteban was originally tested with the original MMPI. His responses from that testing were converted to the MMPI-2 format by J. N. Butcher. The computer-based report for the MMPI-2 norms is provided. The validity scales are shown in the column at left (the column in which the word "MALE" appears). The clinical scales are to the right. The special scales are not included in this version of the profile. (HIGHLIGHT 15.3 on page 585 describes each of these scales.) Based on the scores originally obtained and those you see displayed in the chart, a computer produced the narrative descriptions given here. On page 588 are hypotheses about the psychological functioning of Esteban from a computer-generated report of his Rorschach protocol performed by the Exner Comprehensive Rorschach System.

### Computer-Based Report: The MMPI-2

*Profile Validity*

This MMPI-2 profile should be interpreted with caution. There is some possibility that the clinical report is an exaggerated picture of his present situation. He presented an unusual number of psychological problems and symptoms. His test-taking attitudes should be evaluated to determine if his response pattern is a valid approach to the testing. This extreme response set could result from poor reading ability, confusion, disorientation, stress, or a need to seek attention for his problems. Clinical patients with this profile are often confused, distractible, and show memory problems. Evidence of delusions and thought disorder may be present.

*Symptomatic Pattern*

His MMPI-2 profile reflects a high degree of psychological distress at this time. The client is presenting with a mixed pattern of psychological symptoms. He appears to be tense, apathetic, and withdrawn, and is experiencing some personality deterioration. He seems to be quite confused and disorganized, and probably secretly broods about unusual beliefs and suspicions. Autistic behavior and inappropriate affect are characteristic features of individuals with this profile. Some evidence of an active psychotic process is apparent. He may have delusions and occult preoccupations, and may feel that others are against him because of his beliefs. In interviews, he is likely to be vague, circumstantial, and tangential, and may be quite preoccupied with abstract ideas.

He is having problems concentrating, feels agitated, and is functioning at a very low level of psychological efficiency. He feels apathetic, indifferent, and like a passive participant in life. He also feels that he has little energy left over from mere survival to expend on any pleasure in life. He may be showing signs of serious psychopathology such as delusions, problems in thinking, and inappropriate affect. His long-standing lack of achievement and his work behavior have caused him many problems.

Many individuals with this profile consider committing suicide and he may actually have serious plans for self-destruction.

He experiences some conflicts concerning his sex-role identity, appearing somewhat passive and effeminate in his orientation toward life. He may appear somewhat insecure in the masculine role and may be uncomfortable in his relationships with women.

His response content indicates that he is preoccupied with feeling guilty and unworthy, and feels that he deserves to be punished for wrongs he has committed. He feels regretful and unhappy about life, complains about having no zest for life, and seems plagued by anxiety and worry about the future. According to his response content there is a strong possibility that he has contemplated suicide. A careful evaluation of this possibility is suggested. He views his physical health as failing and reports numerous somatic complaints. He feels that life is no longer worthwhile and that he is losing control of his thought processes. He reports in his response content that he feels things more, or more intensely, than others do.

*Interpersonal Relations*

Disturbed interpersonal relationships are characteristic of individuals with this profile type. He feels vulnerable to interpersonal hurt, lacks trust, and may never form close, satisfying interpersonal ties. He feels very insecure in relationships and may be preoccupied with guilt and self-defeating behavior. Many individuals with this profile are so self-preoccupied and unskilled in sex-role behavior that they never develop rewarding heterosexual relationships. Some never marry.

*Behavioral Stability*

Individuals with this profile type often lead chronically stormy, chaotic lives.

*Diagnostic Considerations*

The most likely diagnosis for individuals with this MMPI-2 profile type is Schizophrenia, possibly Paranoid type, or Paranoid Disorder. Similar clients tend to also have features of an affective disorder. In addition, there seems to be a longstanding pattern of maladjustment that is characteristic of people with severe personality disorders.

Because this behavioral pattern may also be associated with Organic Brain Syndrome or Substance-Induced Organic Mental Disorder, these possibilities should be evaluated.

*Treatment Considerations*

Individuals with this profile may be experiencing considerable personality deterioration, which may require hospitalization if they are considered dangerous to themselves or others.

Psychotropic medication may reduce their thinking disturbance and mood disorder. Outpatient treatment may be complicated by their regressed or disorganized behavior. Multiple-problem life situations and difficulties forming interpersonal relationships make patients with this profile poor candidates for relationship-based psychotherapy. Day treatment programs or other such structured settings may be helpful in providing a stabilizing treatment environment. Long-term adjustment is a problem. Frequent, brief "management" therapy contacts may be helpful in structuring his activities. Insight-oriented or relationship therapies tend not to be helpful for individuals with these severe problems and may actually exacerbate the symptoms. He probably would have difficulty establishing a trusting working relationship with a therapist.

Minnesota Multiphasic Personality Inventory-2. Copyright The University of Minnesota 1943 (renewed 1970), 1989. This form 1989. Reprinted by permission.

Tellegen & Ben-Porath, 1992) has shown that the two versions produce essentially comparable results.

Another kind of objective self-report personality inventory uses the statistical procedure of **factor analysis,** a method for reducing a large array of intercorrelated measures to the minimum number of "factors" necessary to account for the observed overlap or associations among them. Because their scales are a product of such a refinement process, tests of this type are considered to measure purportedly basic and relatively independent personality traits. The goal is to measure one trait at a time with maximum precision and selectivity; a personality profile can then be drawn showing the degree to

                SEMANTIC INTERPRETATION OF THE RORSCHACH
               PROTOCOL UTILIZING THE COMPREHENSIVE SYSTEM
               (COPYRIGHT 1976, 1985 BY JOHN E. EXNER, JR.)

   THE FOLLOWING COMPUTER-BASED INTERPRETATION IS DERIVED ** EXCLUSIVELY **
FROM THE STRUCTURAL DATA OF THE RECORD AND DOES NOT INCLUDE CONSIDERATION OF
THE SEQUENCE OF SCORES OR THE VERBAL MATERIAL. IT IS INTENDED AS A GUIDE FROM
WHICH THE INTERPRETER OF THE TOTAL PROTOCOL CAN PROCEED TO STUDY AND REFINE
THE HYPOTHESES GENERATED FROM THESE ACTUARIAL FINDINGS.

                                * * * * *

1.  THE RECORD APPEARS TO BE VALID AND INTERPRETIVELY USEFUL.

2.  THIS IS THE TYPE OF PERSON WHO IS PRONE TO TRY TO OVERSIMPLIFY STIMULI
    IN ORDER TO MAKE THE WORLD LESS THREATENING AND/OR DEMANDING.  THIS
    BASIC COPING STYLE TENDS TO BE PERVASIVE WHEN NEW SITUATIONS AND/OR
    STRESSES OCCUR. WHEN DONE TO EXCESS, AS APPEARS TO BE THE CASE HERE,
    THE SUBJECT IS LIKELY TO EXPERIENCE FREQUENT SOCIAL DIFFICULTIES
    BECAUSE THE STYLE PROMOTES A NEGLECT OF THE DEMANDS AND/OR
    EXPECTATIONS OF THE ENVIRONMENT.

3.  THIS SUBJECT USUALLY HAS ENOUGH RESOURCE ACCESSABLE TO PARTICIPATE
    MEANINGFULLY IN THE FORMULATION AND DIRECTION OF RESPONSES.  TOLERANCE
    FOR STRESS IS LIKE THAT OF MOST PEOPLE. THAT IS, CONTROLS USUALLY WILL
    NOT FALTER UNLESS THE STRESS IS UNEXPECTED AND INTENSE OR PROLONGED
    UNREASONABLY.

4.  THERE IS EVIDENCE INDICATING THE PRESENCE OF CONSIDERABLE SUBJECTIVELY
    FELT DISTRESS.

5.  THIS SUBJECT TENDS TO INTERNALIZE FEELINGS MUCH MORE THAN IS CUSTOMARY
    AND THIS OFTEN RESULTS IN SUBSTANTIAL DISCOMFORT THAT CAN TAKE THE
    FORM OF TENSION AND/OR ANXIETY.

6.  THIS IS THE TYPE OF PERSON WHO PREFERS TO DELAY MAKING RESPONSES IN
    COPING SITUATIONS UNTIL TIME HAS BEEN ALLOWED TO CONSIDER RESPONSE
    POSSIBILITIES AND THEIR POTENTIAL CONSEQUENCES.  SUCH PEOPLE LIKE TO
    KEEP THEIR EMOTIONS ASIDE UNDER THESE CONDITIONS.

7.  THIS PERSON TENDS TO USE DELIBERATE THINKING MORE FOR THE PURPOSE OF
    CREATING FANTASY THROUGH WHICH TO IGNORE THE WORLD THAN TO CONFRONT
    PROBLEMS DIRECTLY. THIS IS A SERIOUS PROBLEM BECAUSE THE BASIC COPING
    STYLE IS BEING USED MORE FOR FLIGHT THAN TO ADAPT TO THE EXTERNAL
    WORLD.

8.  THIS TYPE OF PERSON IS NOT VERY FLEXIBLE IN THINKING, VALUES, OR
    ATTITUDES.  IN EFFECT, PEOPLE SUCH AS THIS HAVE SOME DIFFICULTY IN
    SHIFTING PERSPECTIVES OR VIEWPOINTS.

    PAGE -2-

================================================================================
 9.  THERE IS A STRONG POSSIBILITY THAT THIS IS A PERSON WHO PREFERS TO
     AVOID INITIATING BEHAVIORS, AND INSTEAD, TENDS TOWARDS A MORE PASSIVE
     ROLE IN PROBLEM SOLVING AND INTERPERSONAL RELATIONSHIPS.

10.  THIS SUBJECT DOES NOT MODULATE EMOTIONAL DISPLAYS AS MUCH AS MOST
     ADULTS AND, BECAUSE OF THIS, IS PRONE TO BECOME VERY INFLUENCED BY
     FEELINGS IN MOST THINKING, DECISIONS, AND BEHAVIORS.

11.  THIS IS A PERSON WHO IS VERY ATTRACTED TO BEING AROUND EMOTIONAL
     STIMULI. THIS MAY POSE A SIGNIFICANT PROBLEM IN ADAPTATION BECAUSE OF
     PROBLEMS IN CONTROL. THAT IS, THE MORE EMOTIONAL STIMULI BEING
     PROCESSED, THE GREATER THE DEMAND FOR EMOTIONAL EXCHANGE. IF THAT
     EXCHANGE IS NOT WELL CONTROLLED, PROBLEMS CAN EASILY OCCUR.

12.  THIS IS AN INDIVIDUAL WHO DOES NOT EXPERIENCE NEEDS FOR CLOSENESS IN
     WAYS THAT ARE COMMON TO MOST PEOPLE.  AS A RESULT, THEY ARE TYPICALLY
     LESS COMFORTABLE IN INTERPERSONAL SITUATIONS, HAVE SOME DIFFICULTIES
     IN CREATING AND SUSTAINING DEEP RELATIONSHIPS, ARE MORE CONCERNED WITH
     ISSUES OF PERSONAL SPACE, AND MAY APPEAR MUCH MORE GUARDED AND/OR
     DISTANT TO OTHERS.

13.  THIS SUBJECT HAS AS MUCH INTEREST IN OTHERS AS DO MOST ADULTS AND
     CHILDREN. HOWEVER, THE SUBJECT DOES NOT APPEAR TO HAVE A VERY
     REALISTIC UNDERSTANDING OF PEOPLE.  INSTEAD, CONCEPTIONS OF OTHERS
     TEND TO BE DERIVED MORE FROM IMAGINATION THAN FROM REAL EXPERIENCE.

14.  THIS SUBJECT APPEARS TO HAVE AN UNUSUAL BODY PREOCCUPATION.

15.  THIS SUBJECT APPEARS TO HAVE A MARKED SEXUAL PREOCCUPATION.

16.  THIS SUBJECT IS VERY PRONE TO INTERPRET STIMULUS CUES IN A UNIQUE AND
     OVERPERSONALIZED MANNER.  PEOPLE SUCH AS THIS OFTEN VIEW THEIR WORLD
     WITH THEIR OWN SPECIAL SET OF BIASES AND ARE LESS CONCERNED WITH BEING
     CONVENTIONAL AND/OR ACCEPTABLE TO OTHERS.

17.  IN SPITE OF THE ABOVE MENTIONED TENDENCY TO MISINTERPRET OR OVERPERSON-
     ALIZE THE INTERPRETATION OF STIMULUS CUES, THE SUBJECT DOES TEND TO
     RESPOND IN CONVENTIONAL WAYS TO SITUATIONS IN WHICH CONVENTIONAL OR
     EXPECTED RESPONSES ARE OBVIOUS AND EASILY IDENTIFIED.

18.  MUCH OF THE COGNITIVE ACTIVITY OF THIS SUBJECT IS LESS SOPHISTICATED
     OR LESS MATURE THAN IS EXPECTED. THIS MAY BE A FUNCTION OF A
     DEVELOPMENTAL LAG, DISORGANIZATION, OR MAY SIMPLY REFLECT A RELUCTANCE
     TO COMMIT RESOURCES TO A TASK.

19.  THIS SUBJECT TENDS TO SCAN A STIMULUS FIELD HASTILY AND NOT
     METHODICALLY.  THESE KINDS OF PEOPLE OFTEN COME TO DECISIONS
     PREMATURELY AND ERRONEOUSLY SIMPLY BECAUSE THEY HAVE NOT PROCESSED ALL
     AVAILABLE INFORMATION ADEQUATELY.  THIS SHOULD NOT BE CONFUSED WITH
================================================================================

```

which several such methodologically rarefied traits are characteristic of an individual, as well as the overall pattern of the traits.

Self-report inventories, such as the MMPI, have a number of advantages over other types of personality tests. They are cost-effective, highly reliable, and objective; they also can be scored and interpreted, or if desired even administered, by computer. A number of general criticisms, however, have been leveled against the use of self-report inventories. As we have seen, some clinicians consider them to be too mechanistic to accurately portray the complexity of human beings and their problems. Also, because these tests require a subject to read, comprehend, and answer verbal material, patients who are illiterate or confused cannot take the test. Furthermore, the individual's cooperation is required in self-report inventories, and it is possible that the subject may distort his or her answers to create a particular impression. The validity scales of the MMPI-2 are a direct attempt to deal with this last criticism.

*Computer Interpretation of Objective Personality Tests.* Scientifically constructed objective personality inventories, because of their scoring formats and emphasis on test validation, lend themselves particularly well to computer scoring and interpretation. The earliest practical applications of computer technology to test scoring and interpretation involved the MMPI. Over 35 years ago, psychologists at the Mayo Clinic programmed a computer to score and interpret clinical profiles. A number of other highly sophisticated MMPI and MMPI-2 interpretation systems have subsequently been developed (Butcher, 1995; Fowler, 1987).

Computer-based MMPI interpretation systems typically employ powerful **actuarial procedures.** In such systems, descriptions of the actual behavior or other established characteristics of many subjects with particular patterns of test scores have been stored in the computer. Whenever a person turns up with one of these test score patterns, the appropriate description is printed out in the computer's evaluation. Such descriptions have been written and stored for a number of different test score patterns, most of them based on MMPI-2 scores.

The accumulation of precise actuarial data for an instrument like the MMPI-2 is difficult, time-consuming, and expensive. This is in part because of the complexity of the instrument itself, since the potential number of significantly different MMPI-2 profile patterns is legion. The profiles of many subjects therefore do not "fit" the profile types for which actuarial data are available. Problems of actuarial data acquisition also arise at the other end, the events or conditions detected or predicted by the instrument. Many conditions that are of vital clinical importance are relatively rare (for example, suicide) or are psychologically complex (for example, possible psychogenic components in a patient's physical illness), thus making it difficult to accumulate a sufficient number of cases to serve as an adequate actuarial

data base. In these situations, the interpretive program writer is forced to fall back on general clinical lore and wisdom to formulate clinical descriptions appropriate to the types of profiles actually obtained. Hence, the best programs are written by expert clinicians who have long experience with the instrument and keep up with its continuously developing research base (Carson, 1990b).

Examples of computer-generated descriptions appear in the evaluations reprinted in HIGHLIGHT 15.4 (pages 586–588). Sometimes the different paragraphs generated by the computer will have elements that seem inconsistent. These inconsistencies result from the fact that different parts of a subject's test pattern call up different paragraphs from the computer. The computer simply prints out blindly what has been found to be typical for people making similar scores on the various clinical scales. The computer cannot integrate the descriptions it picks up, however. At this point the human element comes in: In the clinical use of computers, it is always essential that a trained professional further interpret and monitor the assessment data (American Psychological Association, 1986).

Computerized personality assessment is no longer a novelty, but an important, dependable adjunct to clinical assessment. Computerized psychological evaluations are a quick and efficient means of providing a clinician with needed information early in the decision-making process. Some lingering controversies surrounding computerized psychological assessment are discussed in the "Unresolved Issues" section at the end of this chapter.

## Psychological Assessment in Forensic or Legal Cases

One of the most extensive and fastest-growing applications of psychological tests involves their use in court cases. Applications range from assessments to provide information about the mental state of felons on trial, to assess the psychological adjustment of litigants in civil court cases, and to aid in the determination of child custody in divorce cases.

Many different psychological tests have been employed to evaluate defendants or litigants. If there is a question of cognitive impairment, the WAIS-R or a Halstead-Reitan Neuropsychological Battery might be used. When an individual's psychological adjustment is an issue, the MMPI-2 is the most frequently employed psychological test (Pope, Butcher, & Seelen, 1993) because of its objectivity (less reliant upon interpreter's judgment) and extensive validity base. Due in large part to their scientific acceptability, well-known psychological tests, such as the WAIS-R and MMPI-2, are widely accepted by courts as appropriate assessment instruments. In order for a test to be allowed into testimony, it must be deemed to be an accepted standard. The primary means of assuring that tests are appropriate for court testimony is that they are standardized and are not experimental procedures (Ogloff, 1995; Pope et al., 1993).

The three situations in which psychological tests are most often used in court settings will be illustrated:

Mr. A., a thirty-four-year-old man, on trial for serial rapes, alleged that he was not guilty of the crimes for which he was charged due to insanity. His counsel pleaded that he suffered from multiple personality disorder and that the alleged crimes were committed under the influence of "another personality"; the man was not aware that he was committing a crime. The prosecution employed a team of experts (a psychiatrist and two psychologists) to evaluate the defendant for multiple personality disorder [DID]. The evaluation included a psychiatric interview, personal history, and a battery of psychological tests, including the MMPI, TAT, and Rorschach. The results of the evaluation were not consistent with a diagnosis of multiple personality disorder [DID] but instead suggested malingering.

In a civil law suit, Ms. B., age 29, sought damages from her employer following an incident in which she complained that she had been sexually harassed by the manager of her department. She alleged that on a number of occasions his blatant sexual advances had caused her great anguish and difficulty in her marriage. She claimed that her psychological adjustment during and after the harassment incidents had been extremely difficult and had prevented her from effectively pursing her work. Her therapist supported a diagnosis of post-traumatic stress disorder in her case. (The manager involved in the incident was fired from the company.) Defense attorneys sought a psychological evaluation of Ms. B.

A psychiatric interview and psychological tests were administered, including the Beck Depression Inventory, MMPI-2, TAT, and Rorschach. The conclusions were that she was probably experiencing some post-traumatic symptoms at the time of the evaluation, but that there was evidence that she was exaggerating her symptoms and her disability. Before the trial, the case was settled out of court for a small portion of the original amount claimed.

In a family court case, Mr. & Ms. T. were both seeking custody of their three year old daughter following an acrimonious divorce. During the proceedings, Mr. T., a successful contractor, accused (wrongly as it turned out) Ms. T. of sexually abusing their daughter and sought the termination of her parental rights. A court-appointed psychological evaluation was conducted to assess the emotional stability of Ms. T. and to appraise her suitability as a parent. The court-appointed psychologist did not find that Ms. T. suffered from emotional problems that would make her an unfit mother. Following the trial, the court ruled in favor of full custody for Ms. T. with supervised visits for Mr. T. In addition, the court awarded her $1,000,000 in damages as a result of the false accusation of abuse.

Psychological tests, though for the most part developed for other than court applications, have been found to provide valuable information for court cases—particularly if they contain a means of assessing the person's test-taking attitudes. The MMPI-2, for example, contains several measures that provide an appraisal of the person's cooperativeness or frankness in responding to the test items (Berry et al., 1993). Because many litigants or defendants in criminal cases, when tested, attempt to present themselves in a particular way (for example, to appear disturbed in the case of an insanity plea or impeccably virtuous when trying to present a false or exaggerated physical injury), their motivations to "fake good" or "fake bad" tend to result in noncredible test patterns.

Although psychological tests may be considered very useful in some forensic circumstances, their use has clear limitations (Faust, Ziskin, & Hiers, 1991; Faust, 1994; Heilbrun, 1992). The use of psychological assessment in court is nevertheless widespread and likely to increase in the future, given the increasing number of situations in which mental health adjustment is becoming an issue for courts to evaluate.

## The Use of Psychological Tests in Personnel Screening

Many people who are experiencing personal problems or extreme psychological distress are able to function well enough in their job to get by. Some occupations, however, including those of airline flight crews, police officers, fire fighters, air-traffic controllers, nuclear power plant workers, and certain military specialties require a consistently higher level of psychological performance or greater emotional stability than others; these jobs allow for less personal variation in performance. Emotional problems in such employees can be extremely dangerous to other employees and to society as a whole. For example, someone who holds a key position in a nuclear power plant control room and is experiencing symptoms of severe depression may be significantly impaired, possibly resulting in a failure to recognize problems requiring prompt and decisive action.

The potential impact that mistakes in some occupations can have on the lives and safety of others makes the selection of employees and the monitoring of their mental health particularly critical. The psychological disorders that prompted several Los Angeles police officers to repeatedly strike with their nightsticks a prone and helpless motorist in March 1991, as recorded on videotape, are not simply an internal police matter; they are also a significant issue of concern for all of us. The potential for job failure or for psychological maladjustment under stress is so great in some high-stress occupations that measures need to be taken in the hiring process to evaluate applicants for emotional adjustment.

**Psychological Screening for Emotional Problems** The use of personality tests in personnel screening has a long tradition. In fact, the first formal use of a standardized personality scale, the Woodworth Personal Data Sheet, was implemented to screen out World War I draftees who were psychologically unfit for military service (Woodworth, 1920). Today, psychological tests are widely used for personnel screening in occupations that require a high degree of emotional stability or great public trust. A recent controversial extension of this work is the attempt by some private corporations to assess potential employees for "honesty."

An important distinction needs to be made between personnel selection and personnel screening or, phrased differently, between "screening in" versus "screening out" job candidates. In situations where certain personality characteristics are desired for a particular job, a psychologist would choose instruments that directly assess those qualities, such as the 16 Personality Factor Inventory, which measures "normal" personality characteristics, such as dominance or sociability.

Personnel screening for emotional stability, on the other hand, requires a somewhat different set of assumptions. One assumption is that personality or emotional problems, such as poor reality contact, impulsivity, or low self-esteem, would adversely affect the way in which a person would function in a critical job. In this situation, a psychologist could choose an instrument to assess the presence of psychopathology or maladjustment, such as the MMPI-2. To extend an earlier example, in police officer selection, an applicant with an MMPI-2 profile pattern reflecting tendencies toward extreme aggressiveness, making hasty generalizations about others, and impulsivity would be eliminated from consideration or would undergo further evaluation to determine if these personality factors had resulted in negative job behaviors in the past.

**Issues in Personality Test Job Screening** Before implementing psychological assessment for preemployment screening, an ethically responsible psychologist needs to consider a number of issues to determine both the relevance and appropriateness of the procedures to be used. The following questions need to be addressed:

1. How should the preemployment test be used, or how much weight should be given to a particular test in preemployment decisions? Psychological tests should not be the sole means of determining whether a person is hired. Instruments like the MMPI-2 should be used in conjunction with an employment interview, a background check, an evaluation of previous work record, and so on.

2. Is the use of a psychological test an unwarranted invasion of privacy? Undeniably, many (and perhaps in a certain sense all) psychological tests, especially clinical tests like the MMPI, invade an individual's privacy by asking many personal questions concerning symptoms, attitudes, and lifestyles. Concerns over invasion of privacy have long been expressed, and the question of the appropriateness of these tests in employment selection has been the subject of congressional hearings (see Brayfield et al., 1965). The appropriateness of personality testing in employment decisions has also been tested in court (*McKenna* v. *Fargo*, 1978; *Soroka* v. *Dayton-Hudson*, 1991). In the *McKenna* v. *Fargo* case, the use of the MMPI in screening for some occupations was found to be appropriate while in the *Soroka* v. *Dayton-Hudson* case some of the item content of the original MMPI was considered an invasion of privacy (these items were dropped in the MMPI-2). Therefore, the question becomes one of determining whether a particular test used is a warranted invasion of privacy—that is, determining whether the particular placement decisions being made are consistent with the greater interests of society. For some occupations, such decisions are deemed justifiable; it is considered within the criterion of "public good" that people being placed in positions of high responsibility are emotionally stable according to the best information available.

3. Are the procedures fair to all candidates, including members of ethnic minorities? The question of the fairness of psychological tests in personnel screening is an important one. In order for a psychological test to be considered appropriate (both ethically and legally) for use in personnel selection situations, it must be demonstrated that the test does not unfairly portray or discriminate against ethnic minorities. This question needs to be addressed for each psychological test or personnel procedure used. The tests used must also have a demonstrated validity for the particular test application. In the case of the MMPI, which is the most widely used clinical test in personnel screening, minority group performance has been widely studied (Butcher, 1979; Dahlstrom, Lachar, & Dahlstrom, 1986; King, Carroll, & Fuller, 1977; Wennerholm & Lopez-Roig, 1983). If a person can read the items (if his or her reading level is adequate or a foreign language version is administered, if necessary), the MMPI-2 does not portray or discriminate against various ethnic minority subjects in an unfair manner. Given the more representative normative sample for MMPI-2, it is even less likely than its predecessor to present a problem in this respect.

## A Psychological Case Study: Esteban

In this section, we will illustrate psychological assessment through a diagnostic case study of a young man who presented a complicated clinical picture that was substantially clarified through psychological and neuropsychological assessment. This is an unusual case in several respects: The young man's problems were quite severe and involved both psychological and organic elements; the case involved cross-cultural considerations—the young man was from South America and assessment was done in both English and Spanish (the latter only as necessary); and a number of psychological specialists participated in the assessment study, including a neuropsychologist, a behaviorally oriented clinical psychologist, a Hispanic clinical psychologist, and a psychiatrist.

Esteban, a 21-year-old student from Colombia, South America, had been enrolled in an English language program at a small college in the United States. He had become disruptive in school, evidencing loud, obnoxious behavior in class and quarreling with his roommates (whom he accused of stealing his wallet). After a period of time during which his behavior did not improve, he was expelled from the program. The director of the program indicated that he felt Esteban needed psychological help for his problems, which included not only the behavioral problems but also, reportedly, severe headaches and confused thinking. The director added that Esteban would be considered for readmission only if he showed significant improvement in therapy.

On hearing of his expulsion, Esteban's parents, who were well-to-do international banking entrepreneurs, flew in from South America and arranged for a complete physical examination for him at a well-known medical center in New York. After an extensive medical and neurological examination to determine the source of his headaches and confusion, Esteban was diagnosed as having some "diffuse" brain impairment, but he was found to be otherwise in good health. His parents then sought a further, more definitive neurological examination. The neurologist at the second hospital recommended a psychological and neuropsychological examination because he suspected that Esteban's mild neurological condition would not account for his extreme psychological and behavioral symptoms. He referred the family to a psychologist for assessment and treatment. Because Esteban was experiencing a number of pressing situational problems—for example, his behavior problems continued, he appeared anxious to find a new English program, and, as we will see, he had some hard issues to face about his career aspirations to become a physician—the psychologist decided to begin with therapy immediately, concurrent with the additional assessment evaluation.

**Interviews and Behavior Observations** Esteban was seen in the initial session with his parents. The interview was conducted in English with some translation into Spanish (mostly by Esteban) because the parents knew little English. Throughout the session, Esteban was disorganized and distractible. He had difficulty keeping to the topic being discussed and periodically interrupted his own conversation with seemingly random impulses to show the interviewer papers, books, pamphlets, and the like from his knapsack. He talked incessantly, often loudly. He was not at all defensive about his problems but talked freely about his symptoms and attitudes. His behavior resembled that of a hyperactive child—he was excitable, impulsive, and immature. He did not appear to be psychotic; he reported no hallucinations or delusions and was in contact with reality. He related well with the interviewer, seemed to enjoy the session, and expressed an interest in having additional sessions.

During subsequent interviews, Esteban expressed frequent physical complaints, such as headaches, tension, and sleeping problems. He reported that he had a great deal of difficulty concentrating on his studies. He could not study because he always found other things to do—particularly talking about religion. He was seemingly outgoing and sociable and had no difficulty initiating conversations with other people. He tended, however, to say socially inappropriate things or become frustrated and lose his temper easily. For example, during one family interview, he became enraged and kicked his mother.

**Family History** Esteban's father was a Spanish-Colombian banker in his mid-sixties. He was well-dressed, somewhat passive, though visibly quite warm toward his son. He had his share of difficulties in recent years; severe business problems coupled with two heart attacks had brought on a depressive episode that had left him ineffective in dealing with his business. His wife and her brother, an attorney from Madrid, had to straighten out the business problems. She reported that her husband had had several depressive episodes in the past and that Esteban's moods resembled her husband's in his earlier years.

Esteban's mother was a tense, worried, and somewhat hypochondriacal woman who appeared to be rather domineering. Before the first and second interviews, she handed the therapist, in secret, written "explanations" of her son's problems. Her own history revealed that she was unhappy in her marriage and that she lived only for her children, on whom she doted.

Esteban's brother, Juan, was an engineering student at an American university and apparently was doing well academically and socially. He was one year older than Esteban.

Esteban's childhood had been marked with problems. His mother reported that although he had been a good baby—noting that he had been pretty and happy as a small child—he had changed after age 2½. At about that time, he had fallen on his head and was unconscious for a while; he was not hospitalized. Beginning in the preschool years, he exhibited behavioral problems, including temper tantrums, negativism, and an inability to get along with peers. These problems continued when he began school. He frequently refused to go to school, had periods of aggressive behavior, and appeared in general to be "hyperactive." It appeared that he was probably overprotected and "infantilized" by his mother.

Esteban was quite close to his brother Juan, with whom he reported having had extensive homosexual relations when they were growing up. The "darkest day" in Esteban's life was reportedly when Juan broke off the homosexual relationship with him at age 16 and told him to "go and find men." Although he later carried on a platonic relationship with a woman in Colombia, it was never a serious one. Esteban had strong homosexual urges of which he was consciously aware and attempted to control through a growing preoccupation with religion.

Esteban had been in psychotherapy on several occasions since he was 11 years old. After he graduated from high school, he attended law school in Colombia for a quarter, but dropped out because he "wanted to become a doctor instead." (In Colombia, professional schools are combined with college.) He left school, according to his parents' report, because he could not adapt. He worked for a time in the family business but had difficulty getting along with other employees and was encouraged to try other work. When that failed, his parents sent him to the United States to study English, rationalizing that Colombia was not as good an environment for him as the United States.

**Intelligence Testing** Esteban underwent psychological testing to evaluate further the possibility of neurological deficits and to determine if he had the intellectual capabilities to proceed with a demanding academic career. He scored in the borderline to average range of intelligence on the WAIS-R (English version) and on the WAIS (Spanish version). He was particularly deficient in tasks involving practical judgment, common sense, concentration, visual-motor coordination, and concept formation. In addition, on memory tests, he showed a below average memory ability, such as a poor immediate recall of ideas from paragraphs read aloud (in both English and Spanish). Under most circumstances, people with similar deficits are able to live comfortable, fulfilling lives in careers whose formal intellectual demands are relatively modest. It was clear from the test data and Esteban's behavior during testing that his stated career aspirations—seemingly nurtured by his parents—exceeded his abilities and might well be a factor in much of his frustration.

**Personality Testing** Esteban was given both the Rorschach Test and the MMPI. Both tests have been used extensively with Hispanic subjects. The Rorschach is believed by some to be particularly well-suited for cases like Esteban's because the test stimuli are relatively unstructured and not culture-bound. Esteban's performance on the Rorschach revealed tension, anxiety, and a preoccupation with morbid topics. He appeared to be overly concerned about his health, prone to depression, indecisive and yet at other times impulsive and careless. His responses were often immature and he showed a strong and persistent ambivalence toward females. In some responses, he viewed females in highly aggressive ways—often a fusion of sexual and aggressive images was evident. In general, he demonstrated aloofness and an inability to relate well to other people. Although his Rorschach responses suggested that he could view the world in conventional ways and was probably not psychotic, at times he had difficulty controlling his impulses. Esteban's Rorschach protocol was computer analyzed using the Exner Comprehensive Rorschach System.

Esteban took the original version of the MMPI in both English and Spanish. His MMPI profile was virtually identical in both languages. It has been converted to MMPI-2 format and is reproduced in HIGHLIGHT 15.4 (pages 586–588) along with the MMPI-2-based computer interpretation of his test scores.

**Summary of the Psychological Assessment** Esteban showed mild neurological deficits on neuropsychological testing and borderline intellectual ability. He clearly did not have the academic ability to pursue a medical career. Demanding intellectual tasks placed a great deal of stress on him and resulted in frustration. Furthermore, his poor memory made learning complex material very difficult.

The MMPI-2 interpretation indicated that Esteban's disorganized behavior and symptomatic patterns reflected a serious psychological disorder. Although he was not currently psychotic, both his past behavior and his test performance suggested that he was functioning marginally and that he showed the potential for personality deterioration in some situations.

Esteban's most salient psychological problems concerned his tendency to become frustrated and his ready loss of impulse control. He was volatile and became upset easily. Additionally, it appeared that Esteban's relative isolation during his early years (due in part to his overprotective mother) did not prepare him to function adequately in many social situations. Another important problem area for Esteban was in psychosexual adjustment. The psychological test results and his personal history clearly indicated a gender-identity confusion.

Within the parameters of DSM-IV, Esteban would receive an Axis I diagnosis of organic personality syndrome and an Axis II diagnosis of borderline personality disorder. Furthermore, it was recommended that he undertake social-skills training and that—rather than a career in medicine—he be encouraged to pursue occupational goals more in keeping with his abilities. Psychotropic medication (Lithium and Mellaril) were prescribed for his emotional control problems.

*A Follow-up Note.* Esteban was seen in psychological therapy twice a week and was kept on medication. He was also seen in a social-skills training program for ten sessions. Through the help of his therapist, he was admitted to a less-demanding English program, which seemed more appropriate for his abilities.

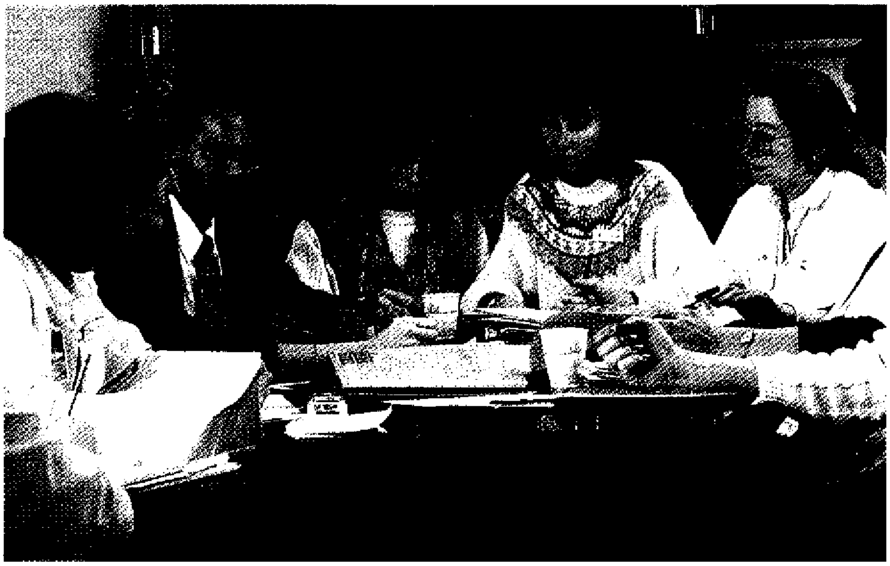
For the first six months, Esteban made considerable progress, especially after his behavior became somewhat stabilized, largely, it appeared, as a result of the medications. He became less impulsive and more in control of his anger. He successfully completed the English classes in which he was enrolled. During this period, he lived with his mother, who had taken up a temporary residence near the college. She then returned to Colombia, and Esteban moved into an apartment with a roommate, with whom, however, he had increasing difficulty.

Several weeks after his mother left, Esteban quit going to therapy and quit taking his medication. He began to frequent local gay bars, at first out of curiosity but later to seek male lovers. At the same time, his preoccupation with religion increased and he moved into a house near campus that was operated by a fundamentalist religious cult. His parents, quite concerned by his overt homosexual behavior (which he described in detail over the phone, adding the suggestion that they visit the gay bar with him), returned to the United States. Realizing that they could not stay permanently to supervise Esteban, they then sought a residential treatment program that would provide him with a more structured living arrangement. All assessment and therapy records were forwarded to those in charge of the residential program.

## THE INTEGRATION OF ASSESSMENT DATA

As assessment data are collected, their significance must be interpreted so that they can be integrated into a coherent working model for use in planning or changing treatment. Clinicians in individual private practice normally assume this often arduous task on their own.

In a clinic or hospital setting, assessment data are usually evaluated in a staff conference attended by members of an interdisciplinary team (perhaps a clinical psychologist, a psychiatrist, a social worker, and other mental health personnel) who are concerned with the decisions to be made regarding treatment. By putting together all the information they have gathered, they can see whether the find-



*In a clinic or hospital setting, assessment data are usually evaluated in a staff conference attended by members of an interdisciplinary team, including, for example, a clinical psychologist, a psychiatrist, a social worker, and a psychiatric nurse. Sharing findings may lead to a diagnostic classification for a patient and a course of treatment. Staff decisions can have far-reaching consequences for patients; as such, it is important that clinicians be aware of the limitations of assessment.*

ings complement each other and form a definitive clinical picture or whether gaps or discrepancies exist that necessitate further investigation.

At the time of an original assessment, integration of all the data may lead to agreement on a tentative diagnostic classification for a patient. In any case, the findings of each member of the team, as well as the recommendations for treatment, are entered in the case record, so that it will always be possible to check back and see why a certain course of therapy was undertaken, how accurate the clinical assessment was, and how valid the treatment decision turned out to be.

New assessment data collected during the course of therapy provide feedback on its effectiveness and serve as a basis for making needed modifications in an ongoing treatment program. As we have noted, clinical assessment data are also commonly used in evaluating the final outcome of therapy and in comparing the effectiveness of different therapeutic and preventive approaches. Summers (1979), among others, has pointed out the importance of assessing a patient's level of functioning prior to hospital discharge. Too often, individuals who cannot function well outside a mental hospital are released into the community with little or no provision for continuing mental health care.

The decisions made on the basis of assessment data may have far-reaching implications for the people under study. A staff decision may determine whether a depressed person will be hospitalized or remain with his or her family; whether divorce will be accepted as a solution to an unhappy marriage or a further attempt will be made to salvage the relationship; or whether an accused person will be declared competent to stand trial. Thus a valid decision, based on accurate assessment data, is of far more than theoretical importance. Because of the impact that assessment can have on the lives of others, it is important that those involved keep several possible factors in mind in evaluating test results:

1. *Potential cultural bias of the instrument or the clinician.* There is the possibility that psychological tests may not elicit valid information from a patient from a minority group (Gray-Little, 1995). A clinician from one sociocultural background may have trouble assessing objectively the behavior of someone from another background, such as a Southeast Asian refugee. It is important to assure, as Timbrook and Graham (1994) have done with the MMPI-2, that the instrument can be confidently used with persons from minority groups.

2. *Theoretical orientation of the clinician.* Assessment is inevitably influenced by a clinician's assumptions, perceptions, and theoretical orientation. For example, a psychoanalyst and a behaviorist might assess the same behaviors quite differently. If the differing assessments should lead to treatment recommendations of significantly differing efficacy for a client's problems, these biases could have serious repercussions.

3. *Overemphasis on internal traits.* Many clinicians overemphasize personality traits as the cause of patients' problems without due attention to the possible role of stressors or other circumstances in their life situations. An undue focus on a patient's personality, which may be encouraged by some assessment techniques, can divert attention from potentially critical environmental factors.

4. *Insufficient validation.* Many psychological assessment procedures have not been sufficiently

validated. For example, unlike many of the personality scales, widely used procedures for behavioral observation and behavioral self-report have not been subjected to strict psychometric validation. The tendency on the part of clinicians to accept the results of these procedures at face value has recently been giving way to a broader recognition of the need for more explicit validation.

5. *Inaccurate data or premature evaluation.* There is always the possibility that some assessment data—and any diagnostic label or treatment based on them—may be inaccurate. Some risk is always involved in making predictions for an individual on the basis of group data or averages; although "schizophrenic" symptoms normatively imply a difficult treatment course, for example, some people who have them recover quickly even without treatment and never experience another episode. Inaccurate data or premature conclusions not only may lead to a misunderstanding of a patient's problem but may close off attempts to get further information, with possibly grave consequences for the patient.

## UNRESOLVED ISSUES
## on the Use of Computerized Assessment

Perhaps the most dramatic innovation in clinical assessment during the last 35 years has been the increasing sophistication and use of computers in individual assessment. As we have seen, computers are effectively used in assessment both to gather information directly from an individual and to put together and evaluate all the information that has been gathered previously through interviews, tests, and other assessment procedures (Bloom, 1992). By comparing the incoming information with data previously stored in its memory banks, a computer can perform a wide range of assessment tasks. It can supply a probable diagnosis, indicate the likelihood of certain kinds of behavior, suggest the most appropriate form of treatment, predict the outcome, and print out a summary report concerning the subject. In many of these functions, a computer is actually superior to a clinician because it is more efficient and accurate in recalling stored material.

With the increased efficiency and reliability accompanying the use of computers in clinical practice, one might expect a near unanimous welcoming of computers into the clinic. This is not the case, however. There is controversy over computerized assessment and a reluctance on the part of some practitioners to use computer-based tests in their practice. We will discuss these general issues in turn.

Concerns have been raised by some psychologists that the widespread use of computer-based assessment procedures is not sufficiently supported by pertinent research (Matarazzo, 1986). In addition, some believe that unvalidated measures have been "oversold" to the point that external professional sanctions or even laws might be required to ensure compliance with standards of good practice (Lanyon, 1984; Matarazzo, 1986). Matarazzo, particularly, feels that reliance on present-day computer-based assessment procedures is problematic because it will increase the cost of health care—with the ready availability of such procedures, clinicians will be tempted to "overtest."

In a rejoinder to Matarazzo's critique, Fowler and Butcher (1986) questioned Matarazzo's position that there are such serious problems with computerized psychological assessment that external controls or legislation are required. Although acknowledging that some largely unvalidated software programs and weak test measures are commercially available, and that practitioners need to exercise care in using computer-based tests, they considered the substantial progress in computer-based psychological testing over the past 35 years to justify further development. According to Fowler and Butcher, many of the problems addressed by Matarazzo have already been resolved and are reflected in the APA guidelines for computer-based assessment (American Psychological Association, 1986). Matarazzo's concern that professionals would "overtest" and increase health care costs was considered by Fowler and Butcher to be overstated. Research has shown that the use of computers in psychological testing can actually reduce the cost of services.

Another of Matarazzo's concerns, in which he called for viewing computerized psychological reports as tools rather than ends in themselves, is an important but not a new concern. The recommendation that computerized tests be considered as working hypotheses and not as final recommendations has been a policy since the earliest days of computer assessment and is a central assumption of the American Psychological Association's (1986) most recent guidelines on computer-based assessment. Practitioners should not employ computer-based interpretations as the ultimate criterion. The final responsibility in a diagnostic study rests with a human clinician—it is she or he who must decide the relevance and utility to the particular case of the various and sometimes contradictory elements of a computer narrative printout.

The second issue raised here is the reluctance of some clinicians to use computer-based test interpretations in spite of their demonstrated utility and low cost. Even though many clinics and independent practitioners acquire microcomputers for recordkeeping and billing purposes, a smaller number incorporate computer-based clinical assessment procedures into their practice. Possible reasons for the underutilization of computer-based assessment procedures include the following:

- Practitioners trained before the computer age may feel uncomfortable with computers or may not have time to become acquainted with them.
- Many practitioners limit their practice to psychological treatment and do not do extensive pretreatment assessments of their cases. Many also have little interest in, or time for, the systematic evaluation of treatment efficacy that periodic formal assessments would facilitate.
- To some clinicians the impersonal and mechanized look of the booklets and answer sheets common to much computerized assessment is contrary to the image and style of warm and personal engagement they hope to convey to clients.
- Some clinicians view computer-based assessment as a threat to their own functioning. Some are concerned, as suggested in Matarazzo's (1986) critique, that computer-assessment specialists seek to replace human diagnostic functioning with automated reports. Others are concerned that unqualified practitioners may gain access to such reports and "set up shop" as competitors.

Some of these concerns are not unlike those expressed by many craftspersons or production personnel in industry when computers and robots come to the workplace. Are human practitioners in danger of being replaced by computers? Not at all. Computers in psychological assessment have intrinsic limitations consigning them to an accessory role in the process; they would not be useful, in fact quite the contrary, if employed as the sole means of evaluation. It is the clinician who must assume the major organizing role and accept the responsibility for an assessment. An unqualified person wholly dependent on computerized reports for carrying on a practice would quickly be identified as incompetent by discerning referral sources, and probably by most self-referred clients; a thriving practice would not be a likely outcome. On the other hand, judicious use of computerized assessment can free up much time for doing those things that can only be accomplished by the personal application of high levels of clinical skill and wisdom (Carson, 1990b).

## SUMMARY

Clinical assessment is one of the most important and complex activities facing mental health professionals. The extent to which a person's problems are understood and appropriately treated depend largely on the adequacy of the psychological assessment. The goals of psychological assessment include identifying and describing the individual's symptoms; determining the chronicity and severity of the problem; evaluating the potential causal factors in the person's background; and exploring the individual's personal resources, which might be assets in his or her treatment program.

Interdisciplinary sources of assessment data include both physical evaluation methods and psychosocial assessment techniques. Because many psychological problems have physical components, either as underlying causal factors or as symptom patterns, it is often important to include a medical examination in the psychological assessment. In cases where organic brain damage is suspected, it is important to have neurological tests—such as an EEG or a CAT, PET, or MRI scan—to aid in determining the site and extent of organic brain disorder. In addition, it may be important to have the person take a battery of neuropsychological tests to determine if or in what manner the underlying brain disorder is affecting his or her mental and behavioral capabilities.

Psychosocial assessment methods are techniques for gathering relevant psychological information for clinical decisions about patients. The most widely used and most flexible psychosocial assessment methods are the clinical interview and behavior observation. These methods provide a wealth of clinical information. They may be subject, however, to extraneous influences that make them somewhat unreliable, and structured interview formats and objective behavior rating scales have been developed to improve their reliability.

Whereas interviews and behavior observations attempt to assess an individual's beliefs, attitudes, and symptoms directly, psychological tests attempt to measure these aspects of personality indirectly. Psychological tests include standardized stimuli for collecting behavior samples that can be compared with other individuals through test norms. Two different personality testing approaches have been developed:

(a) projective tests, such as the Rorschach, in which unstructured stimuli are presented to a subject, who then "projects" meaning or structure on to the stimulus, thereby revealing "hidden" motives, feelings, and so on; and (b) objective tests, or personality inventories, in which a subject is required to read and respond to itemized statements or questions. Objective personality tests provide a cost-effective means of collecting a great deal of personality information rapidly. The MMPI, the most widely used and validated objective personality inventory, and MMPI-2 and MMPI-A, its recently revised offspring, provide a number of clinically relevant scales for describing abnormal behavior.

Psychological tests are widely used in settings other than clinical assessment situations. For example, tests like the MMPI-2, because of their objectivity in describing personality, are widely used in courts for assessing questions such as whether an individual is competent to stand trial or whether a personal injury claimant is suffering from stress following an alleged injury. Another nonclinical setting in which personality assessment is widely used is for personnel screening for positions that require emotionally stable people such as airline pilots, police officers, and nuclear power plant workers.

Possibly the most dramatic recent innovation in clinical assessment involves the widespread use of computers in the administration, scoring, and interpretation of psychological tests. It is now possible to obtain immediate interpretation of psychological test results, either through a direct computer interactive approach or through a modem to a mainframe computer that interprets tests. In the past few years, rapid developments have been taking place in the computer assessment area. It is conceivable that, within the next few years, most clinical assessments will involve computers in some capacity, either for administration, scoring, and interpretation or for completing an entire test battery. Of course, mental health professionals will still play a major role in determining the appropriateness and adequacy of the computer's diagnostic output.

# BIOLOGICALLY BASED THERAPIES

*Johann Knüpfer,* Glory of My Savior. *Knüpfer (1866–1910) lived at home and worked at a variety of manual jobs until he was nearly 30. Thereafter he married, unhappily, and left his wife, eventually becoming a vagrant. He attempted suicide in 1902 and was committed to a mental hospital near Heidelberg. Once there, Knüpfer began to draw. His art is detailed and orderly, and often illustrates religious preoccupations.*

UNRESOLVED ISSUES: HAS PHARMACOLOGY OPENED THE DOOR TO PERSONALITY CHANGE?
SUMMARY
KEY TERMS

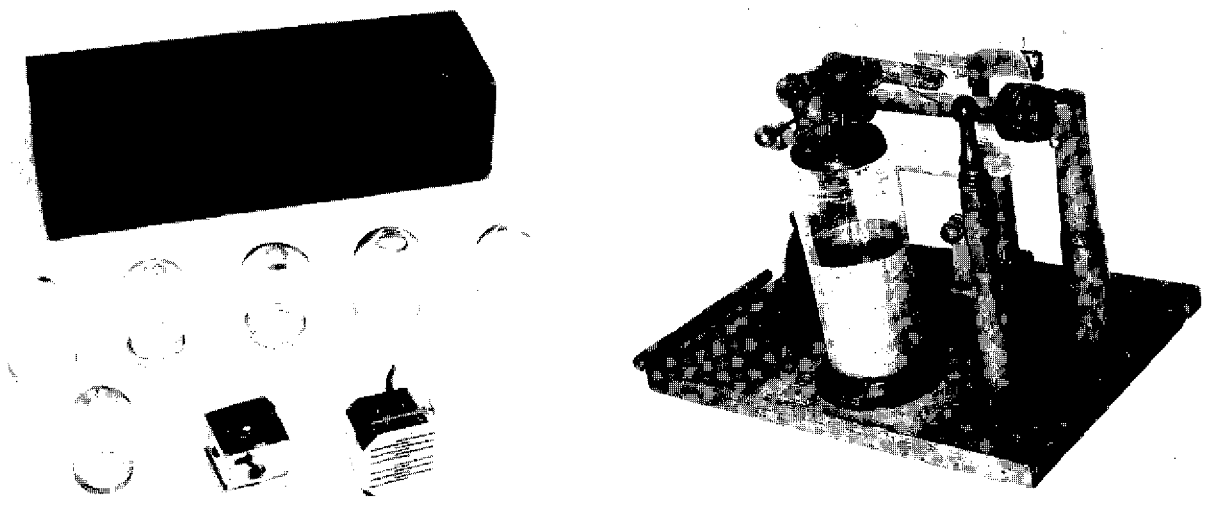
Therapy is directed toward modifying maladaptive behavior and fostering adaptive behavior. The concept of therapy is not new. Throughout recorded history, human beings have tried to help each other with life's problems—including mental disorders—in both informal and formal ways. In Chapter 2 we noted the wide range of procedures that have, throughout history, been advocated for helping the mentally disturbed—from exorcism to incarceration and torture, from understanding and kindness to the most extreme cruelty.

Today both biological and psychological procedures are used in attempts to help individuals overcome psychopathology. In this chapter we will focus on biological methods that have evolved for the treatment of mental disorders, such as the schizophrenias, mood disorders, and disorders in which severe anxiety is central. In the next chapter we will focus on psychological approaches.

## EARLY ATTEMPTS AT BIOLOGICAL INTERVENTION

The idea that a disordered mind might be set straight by treatment directed at the body goes back, as we have seen, to ancient times. From Hippocrates in ancient Greece to Paracelsus in medieval Europe to Kraepelin in Europe at the turn of this century, and on to modern psychiatrists, there have always been those who believed that, ultimately, the cure of mental aberration would be through alteration of an organism's biological state. Today we still have no reliable knowledge of point-to-point correspondence between certain behaviors and particular events in the brain at cellular or subcellular levels. Nonetheless, the dictum "no twisted thought without a twisted molecule," while philosophically and scientifically naive in certain respects, has been deeply internalized by many workers in the mental health field. For them, it is but a small step to conclude that the search for treatment methods should concentrate on finding effective means of rearranging or reconstituting aberrant molecules—of changing the presumed physical substrate of abnormal behavior.

The history of psychiatry reflects interesting, though by today's standards often extreme and primitive, methods of treating mental illness by altering bodily processes. Some have been widely used in several periods of history. For example, ridding the body of unwanted substances by purging (with laxatives and emetics) was a typical treatment in ancient Rome, during the medieval period, and during



*Some of the stranger instruments used for treatment of the mentally ill in the eighteenth and nineteenth centuries are shown here: at left, glass cups and scarificators—which make cuts in the skin—that were used for bleeding patients; at right, an electrostatic generator that was used to shock patients.*

the eighteenth century (Agnew, 1985). In fact, purging was so widespread during some periods, particularly the eighteenth century, that it was a common practice in medicine and among people in general. Other seemingly more barbaric techniques, such as bleeding, have been widely used as treatments of the mentally disordered just as they have been used for a broad range of physical diseases. The use of bleeding was apparently consistent and acceptable to the views of medical science in the eighteenth century. Interestingly, many medical procedures were derived from or paralleled research and development in other sciences. For example, after the discovery of electricity, many efforts to use electrical stimulation to alter mental states ensued. Early electrical devices were used to stimulate patients' nerves, muscles, and organs as a treatment for a variety of illnesses. The rationale behind early somatic efforts to "treat" mental patients was often unclear, although frightening patients out of their madness or punishing the demons within may have been as much a reason as was any belief that an individual's bodily processes were being restored.

In general, as more has been learned in the various subfields of medicine, treatment measures have become more benign and less risky. As researchers come to understand scientifically the nature of a disorder, they typically are then able to develop biological treatments that are more precisely designed to meet the specific problem. The specificity of these new treatments typically means that they have fewer potentially damaging side effects.

The human brain and mind have yielded their secrets grudgingly. As a result, relative to other medical subdisciplines, psychiatry has had a slow and often uncertain development. It should not be surprising, therefore, to find that it has contributed its own array of dubious treatment techniques in the comparatively short history of its recognition as a medical subspecialty. By 1917, with the discovery of Wagner-Jauregg that general paresis, or neurosyphilis, could be curbed by intentionally infecting a patient with malaria (the consequent fevers were lethal to the spirochete), the stage was set for the development of extraordinarily bold and often hazardous new treatments. Wagner-Jauregg later received the Nobel Prize for his discovery. We will look now at two treatments that emerged during this period: the convulsive therapies and psychosurgery.

## Coma and Convulsive Therapies

The first acknowledged medical use of inducing convulsions to treat individuals with mental disorders has been attributed to the Swiss physician-alchemist Paracelsus (1493–1591). He reported a case in which he induced a patient to drink camphor until he experienced convulsions (Mowbray, 1959) in order to cure him of his "lunacy." During the eighteenth century camphor-induced convulsions were used by several physicians to treat mania—in 1764 by Leopold von Aurenbrugger, in 1785 by Oliver, and in 1798 by Weickhardt (see Sandford, 1966). The cure seems to have been forgotten or was not widely adopted, and no use of it was reported during the nineteenth century.

The modern originator of convulsion therapy was Von Meduna, a Hungarian physician, who was apparently unaware of these early efforts to use camphor in the induction of convulsions to treat mania when he published his own observations on inducing epileptic seizures to treat schizophrenia in 1934. Von Meduna speculated—erroneously, as it turned out—that schizophrenia rarely occurred in people with epilepsy. This observation led to the inference that schizophrenia and epilepsy were somehow incompatible, and that one might be able to cure schizophrenia by inducing convulsions. Von Meduna conducted his first experiments on rats and then used camphor to induce convulsions in a schizophrenic patient who relatively quickly regained lucidity after the convulsive therapy. Shortly afterward, Von Meduna began to use a drug called Metrazol rather than camphor to induce convulsions because it operated more rapidly. Von Meduna's work, though not without its critics, provided a great deal of hope that some mental disorders that were previously unresponsive to treatment might now be treatable.

**Insulin Coma Therapy** Rarely used today, **insulin coma therapy** was introduced by Sakel in 1932 as a physiological treatment for schizophrenia and was also used as a treatment for morphine withdrawal. The technique involves administration of increasing amounts of insulin (a hormone that regulates sugar metabolism in the body) daily until a patient goes into "shock"—actually a hypoglycemic coma caused by an acute deficiency of glucose (sugar) in the blood. Coma-inducing doses of insulin are administered daily thereafter until the patient has experienced approximately 50 comas, each an hour or more in duration. The comas are terminated by administering glucose. This treatment causes profound biological and physiological stress, especially to the cardiovascular and nervous systems. The patient must be closely monitored both during and after the comatose state because of a variety of medical complications that may ensue, including some that are fatal.

The results of insulin coma therapy have been generally disappointing. Where patients have shown improvement, it has been difficult to determine whether it was due to the experience of the comas or to some other aspect of the treatment, such as the markedly increased attention of the medical staff. Moreover, patients who do improve tend to be those who would improve readily under other treatment regimens as well; severe, chronic schizophrenic patients remain for the most part unimproved. Finally, the relapse rate for those who improve has been high. With such a record—and in the face of marked medical risks—it is hardly surprising that the use of this therapeutic method has largely disappeared (Kalinowski & Hippius, 1969).

**Electroconvulsive Shock Therapy** Shortly after the discovery of electricity, mild electrical stimulation was used in the treatment of mental disorders. As early as 1849 the physician John Charles Bucknill, working with asylum patients, used electrical stimulation of the skin and potassium oxide to successfully treat patients with melancholic depression (Beveridge & Renvoize, 1988). During the latter part of the nineteenth century, the therapeutic use of electrical stimulation was fairly widespread. Toward the end of the century, however, concern over its safe use resulted in a diminished application of electricity for treatment.

The potential value of electrostimulation therapy was reconsidered after Von Meduna's encouraging work on Metrazol-induced seizures in the treatment of mental disorders. In 1938 two Italian physicians, U. Cerletti and L. Bini, after visiting a slaughterhouse and seeing animals rendered unconscious by electric shock, tried the simplest method of all—that of passing an electric current through a patient's head. The method, which became known as **electroconvulsive therapy (ECT),** is much more widely used today than insulin therapy, mostly because of its effectiveness in alleviating depressive episodes. Although ECT is known to be effective, the mechanism by which it works has never been adequately explained. Some researchers believe that the therapeutic effect is brought about by changes in the levels of certain neurotransmitters or by changes in receptor sensitivity (Fink, 1992).

There are two types of ECT—bilateral and unilateral. The latter is a more recent introduction and is considered, by some, less intrusive. We will review both here. The technique of administering ECT has changed considerably since it was developed by Cerletti and Bini (Khan et al., 1993) although the basic procedure remains similar: An electric current of approximately 150 volts is passed from one side of a patient's head to the other for up to about 1½ seconds. The patient immediately loses consciousness and undergoes marked muscle contractions. Today, anesthetics and muscle-relaxant premedication are usually used to prevent violent contractions and careful, continuous monitoring during the procedure lowers side effects and risk. In the days before such medication was available, the initial seizure was sometimes so violent as to fracture vertebrae, one of several potential complications of this therapy.

After awakening several minutes later, the patient has amnesia for the period immediately preceding the therapy, and is usually somewhat confused for the next hour or so. Normally, a treatment series consists of less than a dozen sessions, although in times past there was widespread overuse of the technique as a means of controlling excited or violent behavior. With repeated treatments, usually administered three times weekly, the patient gradually becomes disoriented, a state that usually clears after termination of the treatments.

Some years ago, a modification in the standard method of administering ECT was introduced. Instead of placing the electrodes on each side of the head in the temple region, thereby causing a transverse flow of current through both cerebral hemispheres, the new procedure involves limiting current flow through only one side of the brain, typically the nondominant (right side, for most people). This procedure is called *unilateral ECT,* and strong evidence shows that it lessens distressing side effects (such as memory impairment) without decreasing therapeutic effectiveness (Daniel & Crovitz, 1983b; Squire, 1977; Squire & Slater, 1978). However, other studies suggest that it may not be as effective as bilateral ECT, and so many suggest reserving the unilateral form for those who have especially prominent memory problems with bilateral ECT (Fink, 1992; Weiner & Krystal, 1994). Evidence gathered in the early 1980s (Daniel & Crovitz, 1983a) also suggested that the use of a lower-energy, pulsating electrical stimulus may produce less mental impairment than the standard treatment, and this is now often used (Fink, 1992; Weiner & Krystal, 1994).

The results of ECT in alleviating some cases of depression are generally acknowledged. A dramatic early example of successful ECT treatments is provided in the autobiographical account of Lenore McCall (1947/1961), who suffered a severe depressive disorder in her middle years.

> Ms. McCall, a well-educated woman of affluent circumstances and the mother of three children, noticed a feeling of persistent fatigue as the first sign of her impending descent into depression. Too fearful to seek help, she at first attempted to fight off her increasingly profound apathy by engaging in excessive activity, a defensive strategy that accomplished little but the depletion of her remaining strength and emotional reserves.
>
> In due course, she noticed that her mental processes seemed to be deteriorating—her memory appeared impaired and she could concentrate only with great difficulty. Emotionally, she felt an enormous loneliness, bleakness of experience, and increasingly intense fear about what was happening to her mind. She came to view her past small errors of commission and omission as the most heinous of crimes and increasingly withdrew from contact with her husband and children. Eventually, at her husband's and her physician's insistence, she was hospitalized despite her own vigorous resistance. She felt betrayed, and shortly thereafter attempted suicide by shattering a drinking glass and ingesting its fragments; to her great disappointment, she survived.
>
> Ms. McCall thereafter spent nearly four years continuously in two separate mental hospitals, during which time she deteriorated further. She was silent and withdrawn, behaved in a mechanical fashion, lost an alarming amount of weight, and underwent a seemingly premature aging process. She felt that she emitted an offensive odor. At this time, ECT was introduced into the therapeutic procedures in use at her hospital.
>
> A series of ECT treatments was given to Ms. McCall over about a three-month period. Then, one day, she woke up in the morning with a totally changed outlook: "I sat up suddenly, my heart pounding. I looked around the room and a sweep of wonder surged over me. God in heaven, I'm well. I'm myself. . . ." After a brief period of convalescence, she went home to her husband and children to try to pick up the threads of their painfully severed lives. She did so, and then wrote the engrossing and informative book from which this history is taken.

At present, the use of ECT is still considered controversial. Public concerns about the treatment as portrayed in novels such as Kesey's *One Flew Over the Cuckoo's Nest* have created negative feelings about its use. Responding to these concerns, the residents of Berkeley, California, voted in November 1982 to ban the use of ECT treatment within that city (*Science News,* November 13, 1982), an action that was later judicially overturned. Though the wisdom of holding public elections on such issues may be questioned, the event demonstrates citizen awareness and concern about the treatment mental patients receive. Moreover, there have been a number of malpractice lawsuits brought against psychia-

*A patient administered electroconvulsive therapy (ECT) today is given sedative and muscle-relaxant premedication to prevent violent contractions. In the days before such medication was available, the initial seizure was sometimes so violent as to fracture vertebrae.*

trists who use ECT, primarily over the failure to obtain appropriate patient consent (Leong & Eth, 1991).

However, some authorities support the use of ECT as the only effective way of dealing with some severely depressed and suicidal patients. Moreover, Mukherjee, Sackeim, and Schnur (1994), evaluating the research on ECT over the past 50 years, concluded that ECT is also an effective treatment for patients with manic disorders who have not responded to pharmacotherapy (80 percent effective overall with difficult to treat patients). For example, Husain and colleagues (1993) reported on the use of a long-term (two-year) treatment of an elderly woman with recurring mania. The authors pointed out that the ECT (81 sessions in all) was the only effective means of controlling her manic episodes and proved to be both safe and cost-effective.

Others within the profession deplore what they consider to be a lack of objective appraisals of ECT. These contrary views would have been easier to dismiss in the 1940s, because little else of proven efficacy was then available. Today there are effective alternative approaches—such as antidepressant medication—in abundance. Moreover, memory impairment resulting from the ECT can remain for some months (Squire, Slater, & Chase, 1975), or, as some attest, even years (Breggin, 1979, 1991). The damage created by electroshock is difficult to estimate in precise terms, but some critics think it could be substantial (Breggin, 1979, Palmer, 1981). It is possible that electroconvulsive treatment destroys a varying number of central nervous system neurons causing such side effects as memory loss or impairment. The extent and permanence of brain damage from ECT has been extensively debated within the field. Weiner (1984) disputes claims of extensive brain damage resulting from ECT, particularly if the ECT is administered unilaterally with "brief pulse" stimulation of the nondominant hemisphere (Weiner et al., 1986). Recent and very carefully done studies using brain imaging techniques have made a compelling case that there is no relationship between ECT (at least properly administered) and brain damage (e.g., Coffey et al., 1991).

In 1985 the National Institute of Mental Health sponsored a Consensus Development Conference on electroconvulsive therapy to evaluate the issues surrounding the use of ECT (National Institute of Mental Health, 1985a). A panel of experts in psychiatry, psychology, neurology, psychopharmacology, epidemiology, and law, along with several laypersons, considered evidence as to (a) the effectiveness of ECT for patients with various disorders; (b) the risks of ECT; (c) the indications for administration of ECT; and (d) the best ways to implement ECT with patients.

The panel recognized a number of potential risks associated with the use of ECT and concluded that these risks have been virtually eliminated. Mortality following ECT, a significant problem in the early days of the treatment, has also been significantly reduced to about 2.9 deaths per 10,000 patients. The injury and mortality rates are considered comparable to other somatic treatments, such as barbiturate anesthetics. The panel reached a number of conclusions as to which disorders responded best to ECT. They agreed that the effect of ECT was well established for some types of depression, particularly delusional depression and "endogenous" depression. They also concluded that ECT can be effectively used with some types of manic disorders, particularly acute mania. On the other hand, they found that ECT was not particularly effective with some depressions, such as dysthymic disorder. Although ECT is sometimes used with certain types of schizophrenia, the evidence for effectiveness is not convincing. The NIMH consensus panel concluded that relapse rates following ECT were high unless the treatment was followed by maintenance doses of antidepressant medication.

More recently, the American Psychiatric Association (1992) and the Canadian Psychiatric Association (Enns & Reiss, 1992) have established clearer guidelines and standards for using ECT, training staff who conduct ECT, and policies for obtaining informed consent from patients.

Despite all the questions and controversy, the therapeutic efficacy of ECT, at least for some depressions and acute mania, is well established in the research literature (Abrams, 1988, 1994; Fink, 1979; Scovern & Kilman, 1980) and in personal testimonials from those who have been helped by it (Endler, 1990).

## Psychosurgery

Brain surgery used in the treatment of functional or central nervous system disorders has been called **psychosurgery.** Mindus and colleagues (1993), however, object to this term because the "psyche" is not being operated upon. They prefer to use the term *neurosurgery* instead. We will use both terms in this text to refer to brain surgery for emotional disorders.

Although brain surgery was used occasionally in the nineteenth century to treat mental disorders by relieving pressure in the brain (Berrios, 1990), it was not considered a treatment for psychological problems until this century. In 1935 in Portugal, Antonio Moniz introduced a psychosurgical procedure in which the frontal lobes of the brain were severed from the deeper centers underlying them. This technique eventually evolved into an operation known as **prefrontal lobotomy.** This operation stands as a dubious tribute to the extremes to which professionals have sometimes been driven in their search for effective treatments for the psychoses. In retrospect, it is ironic that this procedure—which results in permanent structural changes in the brain of the patient and has been highly criticized by many within the profession—won Moniz the 1949 Nobel Prize in Medicine.

In the two decades between 1935 and 1955 (after which the new antipsychotic drugs became widely available), tens of thousands of mental patients in this country and abroad were subjected to prefrontal lobotomy and related neurosurgical procedures. In fact, in some settings, as many as 50 patients were treated in a single day (Freeman, 1959). As is often the case with newly developed therapeutic techniques, initial reports of results tended to be enthusiastic, downplaying complications (including a 1–4 percent death rate) and undesirable side effects. It was eventually recognized, however, that the "side effects" of psychosurgery could be very undesirable indeed. In some instances they included a permanent inability to inhibit impulses; in others, an unnatural "tranquility," with undesirable shallowness or absence of feeling. By 1951 the Soviet Union had banned all such operations; though rarely performed today, they are still permitted by law in the United States and in many other countries and, as we will see, have been making a comeback in modified form as a psychiatric treatment today for some difficult-to-treat disorders. See HIGHLIGHT 16.1 for an illustration of the sometimes tragic outcome of lobotomy.

The advent of the major antipsychotic drugs caused an immediate decrease in the widespread use of psychosurgery, especially prefrontal lobotomy. Such operations are rare today and are used only as a last resort for the intractable psychoses, severely and chronically debilitating obsessive-compulsive disorders, and occasionally for the control of severe pain in cases of terminal illness.

Despite the evolution of more precise techniques, continuing concern has been voiced about such operations. In the mid-1970s the Congress of the United States called a special national commission to evaluate their effects. The commission's report indicated some surprisingly beneficial effects that had been achieved with modern psychosurgery—for example, the alleviation of chronic depression—but it also warned that such benefits were often achieved at the expense of the loss of certain cognitive capacities. The commission recommended that cautious exploration of these techniques be continued with selected patients (Culliton, 1976).

The debate about the benefits and potential damage resulting from psychosurgery received a thorough airing in two fascinating books by Elliot Valenstein (1980, 1986). Valenstein scrutinized the procedures of psychosurgery—and by implication other "brain-disabling" therapies—in relation to the psychiatric, ethical, legal, and social issues they raise. In the 1986 book *Great and Desperate Cures,* Valenstein examined the historical basis of psychosurgery and explained how an unproven and potentially life-threatening treatment could emerge in a field devoted to scientific explanation and become an accepted treatment method with little empirical justification. Factors underlying this premature and "desperate" acceptance of psychosurgery included psychiatry's need to "gain respectability" as a medical science by having an organic-surgical treatment method; the professional rivalry between psychiatry, neurology, and neurosurgery; and the need to provide a cost-effective treatment and maintain control over mental hospitals.

When psychosurgery is employed today it is a far more circumspect procedure than in the heyday of lobotomies. Patients are more carefully screened and given more careful postoperative monitoring. Moreover, today the permanent damage to the brain has been substantially minimized and fewer detrimental side effects follow. Modern surgical techniques involve the selective destruction of minute areas of the brain; for example, in the "cingulotomy" procedure—which seems to relieve the subjective experience of pain, including "psychic" pain—a small bun-

16.1

## The Accomplishments and Subsequent Tragedy of Rosemary Kennedy

One of the tragic victims of the zeal to perform prefrontal lobotomies to alleviate behavior problems was Rosemary Kennedy, the sister of President John F. Kennedy and Senators Robert and Edward Kennedy. Rosemary was the third child of Joseph and Rose Kennedy, born during the height of the flu epidemic of 1918. She was a beautiful baby, with a sweet temperament, but as she grew, her mother became more and more concerned about her developmental delays compared to her brothers and sisters. When the family finally concluded that Rosemary likely was retarded since birth from unknown causes, the best experts in the country at the time could offer no guidance: "We went from doctor to doctor. From all, we heard the same answer: 'I'm sorry, but we can do nothing.' For my husband and me it was nerve-racking and incomprehensible" (Goodwin, 1988, p. 416).

Rose Kennedy and the family rebelled against the suggestion that Rosemary be institutionalized. Instead, she was kept at home with the benefit of a special governess and many private tutors. She participated fully in the Kennedy's family activities, and she made considerable progress. Doris Kearns Goodwin (1988), a biographer of the Fitzgerald and Kennedy families, described an arithmetic paper that the 9-year-old Rosemary completed on February 21, 1927. She correctly answered several multiplication (428 times 32) and division (3924 divided by 6) problems. By the age of 18 years, Rosemary had obtained a fifth-grade level in English and remained at the fourth-grade level in math that she had obtained by age 9.

Because of the considerable stigma associated with mental retardation at the time, Rosemary's parents kept her condition hidden from those outside the family, a major task given the scrutiny of the family by the press. Although her parents and siblings were always nearby to protect her, Rosemary developed the social skills needed to be presented successfully as a debutante and later to the King and Queen of England at Buckingham Palace. The British press complimented Rose Kennedy for her beautiful daughters, never even noticing Rosemary's mental retardation.

Unfortunately, Rosemary's behavior deteriorated around the beginning of World War II when the family returned to the United States from England, where Joseph Kennedy had been ambassador. There are several possible explanations for this deterioration, including her increasing frustration about not being able to do all the things her siblings were able to do and having to leave the school in England where she had felt successful. The 21-year-old Rosemary became quite violent and frequently ran away from home or her convent school. There was considerable concern for her safety, and Joseph Kennedy—without Rose's knowledge—turned to the medical experts of the time, searching for a solution.

These experts convinced Joe that the miracle treatment lay in prefrontal lobotomy. Rosemary Kennedy became one of the thousands submitted to that "desperate" cure. In Rosemary's case, the surgery was a tragic failure—all her previous accomplishments were wiped out, leaving little of her former personality and adaptive ability intact: "They knew right away that it wasn't successful. You could see by looking at her that something was wrong, for her head was tilted and her capacity to speak was almost entirely gone. There was no question now that she could no longer take care of herself and that the only answer was an institution." (Ann Gargan King, a cousin, as reported by Goodwin, 1988, p. 744)

dle of nerve fibers connecting the frontal lobes with a deeper structure known as the limbic system is interrupted with virtually pinpoint precision (Jenike et al., 1991). Another type of neurosurgery—the "capsulotomy" procedure, originally developed in Sweden—is a surgical operation that involves drilling very small holes in the patient's skull (employing careful measurement) and inserting tiny thermal electrodes in the brain. The electrodes are caused to heat up, which destroys the adjacent cellular structures. Reportedly, patients do not experience subjective distress from the procedures (Meyerson & Mindus, 1988; Sweet & Meyerson, 1990). Contemporary use of neurosurgery in the treatment of severe mental disorders is recommended only for patients who have not responded to all other forms of treatment considered standard for the disorder for a period of five years, and who are experiencing extreme disabling symptoms. Patients are accepted for neurosurgical treatment only if they are rationally capable of understanding the procedure and provide informed consent.

*Shown here is a demonstration of a transorbital lobotomy, which was used extensively in this country from the 1940s until the late 1950s. First, a doctor administers ECT to anesthetize the patient (left). Immediately following ECT, another doctor performs the actual lobotomy (right). It is estimated that tens of thousands of patients were subjected to such procedures, resulting in permanent brain damage (which was, after all, the actual intent of the procedure) and sometimes death.*

Although there have not yet been enough controlled studies of these new psychosurgery techniques published at this time to warrant firm conclusions, research has been encouraging. For example, Mindus and colleagues (1993) described an overall satisfactory result of psychosurgery in 253 severe obsessive-compulsive patients. About two-thirds of these patients were found to be symptom-free or much improved over their previous symptom levels after the surgery. Also, important to the acceptability of an experimental procedure is the relative absence of negative side effects. In this respect, Mindus and colleagues (1993) reported that no deaths occurred as a result of the psychosurgery and that the risk of suicide (often reported as a frequent outcome of psychosurgery in the past) was not found to be increased in patients undergoing the procedure.

## THE EMERGENCE OF PHARMACOLOGICAL METHODS OF TREATMENT

A long-term goal of medicine has been to discover drugs that can effectively combat the ravages of mental disorder. This goal, one of the pursuits of **pharmacology,** the science of drugs, has until the last few decades remained elusive. Early efforts in this direction were limited largely to a search for drugs that would have soothing, calming, or sleep-inducing effects—drugs that would make it easier to manage distraught, excited, and sometimes violent patients. Little thought was given to the possibility that the status and course of the disorder itself might actually be brought under control by appropriate medication; the focus was on rendering a patient's overt behavior more manageable and thereby making restraints, such as straitjackets, unnecessary.

As the field of psychopharmacology developed, many such compounds were introduced and tried in the mental hospital setting. Almost without exception, however, those that produced the desired calming effects proved to have serious shortcomings. At effective dosage levels, they often produced severe drowsiness if not outright sleep, and many of them were dangerously addicting. On the whole, little real progress was made in this field until the mid-1950s, at which point, as we will see, a genuine revolution in the treatment of the more severe disorders occurred. This breakthrough was followed shortly by the discovery of drugs helpful in the treatment of the less severe anxiety-based disorders, and also by recognition of the therapeutic benefits of antidepressants and lithium salts for the mood disorders.

### Types of Drugs Used in Therapy

In this section we will trace the discovery of the four types of chemical agents now commonly used in therapy for mental disorders—antipsychotic drugs, antidepressant drugs, antianxiety drugs (minor tranquilizers), and lithium. These drugs are sometimes

*Straitjackets and other forms of restraint were used on out-of-control patients before the advent of antipsychotic drugs.*

referred to as ***psychotropic*** (literally mind-turning or mind-altering) ***drugs***, in that their main effect is on an individual's mental life. As we examine drugs used in therapy, it is important to remember that people differ in how rapidly they metabolize drugs—that is, in how quickly their bodies break down the drugs once ingested. What this means is that people differ, too, in what dosage of a drug they may need to experience the desired therapeutic effect. Determining correct dosage is a critical factor of drug therapy because too much or too little of a drug can be ineffective and (in the case of too much) even life-threatening, depending on the individual.

**Antipsychotic Drugs** The **antipsychotic drugs** as a group are sometimes called ***major tranquilizers***, but this term is somewhat misleading. They are used with the major disorders, such as the schizophrenias, but they do more than tranquilize. Though they do indeed produce a calming effect on many patients, their unique quality is that of somehow alleviating or reducing the intensity of psychotic symptoms, such as delusions and hallucinations. In some cases, in fact, a patient who is already excessively "tranquil" (for example, withdrawn or immobile) becomes active and responsive to the environment under treatment by these drugs. In contrast, the antianxiety drugs, to be described shortly, are effective in reducing tension without in any way affecting psychotic symptoms.

Although the benefits of the antipsychotic drugs have often been exaggerated, it is difficult to convey the truly enormous influence they have had in altering the environment of the typical mental hospital. One of the authors, as part of his training, worked several months in the maximum security ward of one such hospital just before the introduction of this type of medication in 1955. The ward patients fulfilled the common stereotypes of individuals "gone mad." Bizarreness, nudity, wild screaming, and an ever-present threat of violence pervaded the atmosphere. Fearfulness and a nearly total preoccupation with the maintenance of control characterized the staff's attitude. Such an attitude was not unrealistic in terms of the frequency of serious physical assaults by patients, but it was hardly conducive to the development or maintenance of an effective therapeutic program.

Then, quite suddenly—within a period of perhaps a month—all of this dramatically changed. The patients began receiving the new antipsychotic medication. The ward became a place in which one could get to know one's patients on a personal level and perhaps even initiate programs of "milieu therapy," a form of psychosocial therapy in which the entire facility is regarded as a therapeutic community, and the emphasis is on developing a meaningful and constructive environment in which the patients participate in the regulation of their own activities. Promising reports of changes in hospital environments began to appear in the professional literature. A new era in hospital treatment had arrived, aided enormously and in many instances actually made possible by the development of these extraordinary drugs.

The beginnings of this development were quite commonplace. For centuries, the root of the plant ***rauwolfia*** (snakeroot) had been used in India for the treatment of mental disorders. In 1943 the ***Indian Medical Gazette*** reported improvements in manic reactions, schizophrenia, and other types of psychopathology following the use of ***reserpine***, a drug derived from rauwolfia. Early enthusiasm for the drug was tempered, however, by the finding that it also might produce low blood pressure, nasal congestion, and, perhaps most seriously, severe depression. Reanalysis of this latter finding suggested that the danger of serious depression was mainly for patients with a prior history of depression (Mendels & Frazer, 1974). Reserpine is now used mainly for the control of hypertension.

Meanwhile, the first of the phenothiazine family of drugs, ***chlorpromazine*** (Thorazine), was being synthesized in the early 1950s by one of the major pharmaceutical houses. It was first marketed at about the same time that reserpine was introduced, and it quickly proved to have virtually the same benefits but fewer undesirable side effects. Chlorpromazine soon became the treatment of choice for schizophrenia.

The remarkable early successes reported with chlorpromazine led quickly to a bandwagon effect among other pharmaceutical companies, who began to manufacture and market their own variants of the basic phenothiazine compound. Some of the best known variants are trifluoperazine (Stelazine), promazine (Sparine), prochlorperazine (Compazine), thioridazine (Mellaril), perphenazine (Trilafon), and fluphenazine (Prolixin). Currently, too, there are at least six classes of nonphenothiazine antipsychotic drugs available in the United States, of which the best known is haloperidol (Haldol). This diversity becomes less bewildering when it is remembered that virtually all of the antipsychotics accomplish a common biochemical effect, namely the blocking of dopamine receptors, as was noted in Chapter 12.

With persistent use or at high dosage, however, all of these preparations have varying degrees of troublesome side effects, such as dryness of the mouth and throat, muscular stiffness, jaundice, and a Parkinson-like syndrome involving tremors of the extremities and immobility of the facial muscles. Which side effects develop appears to depend on the particular compound used in relation to the particular vulnerabilities of the treated patient. Many of these side effects are temporary and may be relieved by substituting another drug of the same class, by switching to a different class of drug, or by reducing the dosage. We should also note that some schizophrenic individuals, particularly those with negative symptoms or chronic schizophrenia, do not respond to antipsychotic drug therapy and may indeed be made worse by it (Buckley, 1982).

For certain patients, a particularly troublesome side effect of long-term antipsychotic drug treatment is the development of a disfiguring disturbance of motor control, particularly of the facial muscles, known as **tardive dyskinesia.** Symptoms of tardive dyskinesia, which often seem to disappear when a patient is asleep, are both dramatic to an observer and disabling to the patient. The symptoms involve involuntary movements of the tongue, lips, jaw, and extremities. An individual with tardive dyskinesia may show involuntary limb movement and usually shows characteristic chewing movements, lip smacking, and sucking of the mouth. The disturbance is believed to be due to an imbalance in dopamine and acetylcholine activity in the brain, secondary to alterations in receptor sensitivity by antipsychotics and other drugs commonly used in combination to control their side effects. Side effects of tardive dyskinesia can occur months to years after the antipsychotic drug treatment is initiated and after the treatment has been stopped or the drug reduced in dosage.

*The introduction of antipsychotic drugs in hospital treatment of the mentally ill was a major breakthrough in altering the environment of the typical mental hospital.*

Recent efforts have been undertaken to study possible characteristics of schizophrenic persons who might develop medication side effects such as tardive dyskinesia (Leonard et al., 1992). Crow (1980) proposed a distinction (noted in Chapter 12) between positive symptoms such as hallucinations, delusions, and thinking disturbance and negative symptoms such as poverty of speech and flat affect. Crow and colleagues (1983) reported that abnormal involuntary movements are associated with the presence of negative symptoms, a finding that has been supported by more recent research (Liddle et al., 1993). Moreover, there is some indication that abnormal movements are associated with aging (Kane & Smith, 1982). These studies suggest that different pathological factors might contribute to the development of schizophrenia and the manifestation of symptoms.

Tardive dyskinesia develops in approximately 10–20 percent of people who take phenothiazines for long periods of time (Kane et al., 1986; Torrey, 1983). It may occur in an even higher percentage of alcohol-abusing schizophrenics (Dixon et al., 1992; Olivera, Kiefer, & Manley, 1990) and is especially likely in people over 55. The manifestation of the disturbance appears to fluctuate in patients over time (Bergen et al., 1989). The use of antipsychotic medications in treatment is usually discontinued if a patient shows symptoms of tardive dyskinesia. Although there are medications that control the symptoms of tardive dyskinesia, drug therapy is generally not recommended (American Medical Association, 1986). In some cases where the patient continues to display psychotic symptoms, the use of antipsychotic medication treatment may be resumed; however, discontinuation of the treatment is recommended if any symptoms of tardive dyskinesia reappear. To reduce the chances of this disturbance during the drug treatment of chronic schizophrenics, clinicians are more frequently using what is called "target dosing" (Rosen, 1986), which entails administering a drug when symptoms appear or are likely to appear rather than giving continuous dosages, as commonly practiced in the past.

Another trend in the treatment of schizophrenia involves the application of lower doses of standard drugs to reduce negative side effects. Hogarty and colleagues (1988) have shown that lower-dose-treated schizophrenics actually showed more improvement than normal-dose-treated patients in terms of many observable behaviors. Moreover, relapse rates were found to be comparable to patients treated with normal doses.

The range of effects achieved by the antipsychotic drugs may be illustrated by two brief case histories of patients who served as subjects in a clinical research project designed to evaluate differing treatment approaches to the schizophrenias (Grinspoon, Ewalt, & Shader, 1972):

> Ms. W. was a 19-year-old, white, married woman who was admitted to the treatment unit as a result of gradually increasing agitation and hallucinations over a three-month period. At the outset of her hospitalization, Ms. W. continued to have auditory and visual hallucinations and appeared frightened, angry, and confused. She believed that she had a unique relationship with God or the devil. Her thought content displayed loosening of associations, and her affect was inappropriate to this content. Her condition continued to deteriorate for more than two weeks, at which point medication was begun.
>
> Ms. W. was assigned to a treatment group in which the patients were receiving thioridazine (Mellaril). She responded dramatically during the first week of treatment. Her behavior became, for the most part, quiet and appropriate, and she made some attempts at socialization. She continued to improve, but by the fourth week of treatment began to show signs of mild depression. Her medication was increased, and she resumed her favorable course. By the sixth week she was dealing with various reality issues in her life in a reasonably effective manner, and by the ninth week she was spending considerable time at home, returning to the hospital in a pleasant and cheerful mood. She was discharged exactly 100 days after her admission, being then completely free of symptoms.

> Mr. S., the eldest of three sons in a fairly religious Jewish family, was admitted to the hospital after developing marked paranoid ideation and hallucinations during his first weeks of college. He had looked forward to going to college, an elite New England school, but his insecurity once on campus caused him to become unduly boastful about his prowess with drinking and women. He stayed up late at night to engage in "bull sessions" and neglected his studies and other responsibilities. Within ten days he panicked about his ability to keep up and tried frantically to rearrange his course schedule and his life, to no avail.
>
> His sense of incompetence was transformed over time into the idea that others—including all the students in his dormitory—were against him, and that fellow male students were perhaps flirting homosexually with him. By the time of his referral to the college infirmary, he was convinced that the college was a fraud he would have to expose, that the CIA was plotting against him, and that someone was going to kill him. He heard voices and smelled strange odors. He also showed a marked loosening of associations and flat, inappropriate affect. At the time of his transfer to the hospital, he was diagnosed as an acute paranoid schizophrenic.
>
> Mr. S. was assigned to a treatment group receiving haloperidol (Haldol). His initial response to treatment was rapid and favorable, but

observers noted that his behavior remained immature. Then suddenly during the fifth week of treatment, he became tense, negativistic, and hostile. Thereafter, he gradually became less defiant and angry, and he responded well to a day-care program prescribed by his therapist, although he was nervous and apprehensive about being outside the hospital. He was discharged as improved ten weeks after the initiation of his drug therapy.

Three months later Mr. S. was readmitted to the hospital. Although he had done well at first, he had begun to deteriorate concurrently with his doctor-monitored withdrawal from haloperidol. His behavior showed increasing signs of a lack of effective control. He began to set random fires and was described by the investigators as "sociopathic." Two days after his readmission, he signed himself out of the hospital "against medical advice." His parents immediately arranged for his confinement in another hospital, and the investigators subsequently lost contact with him.

Recent research with treatment-resistant schizophrenics has focused on possible alternative drugs. One such compound that differs from the phenothiazines, clozapine (a dibenzodiazepine), has produced very promising results (Breier et al., 1994; Marder et al., 1993). Kane and colleagues (1988) studied the therapeutic effects of clozapine with a large group of treatment-resistant schizophrenics and found the treatment effects modestly encouraging. Thirty percent of the treatment-resistant patients improved under the regimen and no negative side effects were noted. More recent research (Meltzer, 1992) has suggested that up to 60 percent of phenothiazine-resistant patients may benefit from clozapine if it is continued for several months. Further research on the side effects of this drug is indicated, however, because some studies have found that about 1–2 percent of the patients taking the drug develop an immune deficiency that is life-threatening and that has resulted in the death of several patients.

Even though clozapine has been heralded as the most effective treatment for schizophrenia, its use requires considerable caution and careful monitoring (Marder et al., 1993). The potentially lethal characteristic of the drug requires a highly structured blood-monitoring system along with the medication to guard against its misuse. Unfortunately, the cost of the drug in combination with this monitoring system makes the treatment expensive and has threatened to drastically limit its availability for many patients needing the drug (Winslow, 1990). Such economic considerations may be shortsighted. Meltzer and colleagues (1993) have shown that clozapine can be very cost-effective by reducing the need for rehospitalization. Two newer antipsychotic drugs awaiting release from the Food and Drug Administration at this time are risperidone and remosipride. These drugs, similar to clozapine, suppress psychotic thinking without many of the negative side effects associated with antipsychotic medications such as the phenothiazines, particularly tardive dyskinesia (Meltzer, 1993).

**Antidepressant Drugs** The **antidepressant drugs** made their appearance shortly after the introduction of reserpine and chlorpromazine. Although many of these drugs were initially introduced as antidepressants they have also been found to be effective with other disorders. There are several basic classes of antidepressant compounds:

The first group, the *monoamine oxidase (MAO) inhibitors,* include isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate) (see Chapter 6). These drugs inhibit the activity of *monoamine oxidase,* an enzyme present in the synaptic cleft that helps break down the monoamine neurotransmitters (such as serotonin and norepinephrine) that have been released into the cleft. As discussed in Chapter 6, the early monoamine hypothesis of depression proposed that these drugs work through increasing the availability of the monoamines by working against their breakdown. Today we know that their effects are much more complex than this, but we still don't know exactly how they operate to reduce depression.

Another group of antidepressants, the *tricyclics or TCAs,* operate to inhibit the re-uptake of serotonin and norepinephrine once they have been released into the synapse. As discussed in Chapter 6, the theory that these drugs work by increasing norepinephrine activity is now known to be oversimplified. In particular, although the immediate short-term effects of tricyclics are to increase the availability of norepinephrine and serotonin in the synapses, the long-term effects of these drugs (when they begin to have their clinical effects after two to four weeks) are to produce functional decreases in available norepinephrine and serotonin (Goodwin & Jamison, 1990; Prior & Sulser, 1991; Shelton et al., 1991; Siever & Davis, 1985; Thase et al., 1985). It is also known that when the tricyclics are taken for several weeks they act to decrease the number and sensitivity of certain types of receptors and to increase the responsiveness of others (Goodwin & Jamison, 1990; McNeal & Cimbolic, 1986; Shelton et al., 1991).

Of the main classes of antidepressants, the tricyclics and their variants have been most often used. This is largely because other available medications such as the MAO inhibitors are more toxic and require troublesome dietary restrictions; in addition, they are widely believed to have less potent therapeutic effects. Nevertheless, some patients who do not respond favorably to tricyclics will subsequently do well on an MAO inhibitor. Although the MAO inhibitors are more toxic than the tricyclics, the tricyclics also have unpleasant side effects such as dry mouth, tiredness, dizziness, blurred vision, constipation, and occasional erectile dysfunction in men. Therefore, some patients do not continue taking the drug long enough for it to have its antidepressant effect. In addition, because these drugs are highly toxic when taken in large doses, there is some risk in prescribing them for suicidal patients who might use them for an overdose. Commonly used tricyclics are imipramine (Tofranil), amitriptyline (Elavil), and nortriptyline (Aventyl).

Tricyclic antidepressant drugs continue to be developed, tested, and marketed at a high rate. Among the more recent entrants to the field are amoxapine (Asendin) and maprotiline (Ludiomil). Amoxapine is a tricyclic related to certain of the antipsychotic drugs and thus may prove to have a special role in the treatment of schizoaffective disorder.

A "second generation" antidepressant, chemically unrelated to other antidepressant medications, are the ***serotonin selective re-uptake inhibitors or SSRIs,*** such as fluoxetine (Prozac), and the ***aminoketones*** (Bupropion). As their name implies, the SSRIs serve to inhibit the re-uptake of serotonin following its release into the synapse. Unlike the tricyclics, they *selectively* inhibit the re-uptake of serotonin rather than inhibiting the re-uptake of both serotonin and norepinephrine. One SSRI, fluoxetine—better known by the trade name Prozac—has become the preferred antidepressant drug in the 1990s (see the "Unresolved Issues" section). Prozac is thought to be a relatively "safe" drug in that it is not considered physiologically addicting and is not found to be fatal in overdose as the tricyclics can be. Clinical trials with fluoxetine have reported that patients tend to improve after about three weeks of treatment with the drug. Several adverse side effects of Prozac were reported, particularly nausea, nervousness, and insomnia (Cole & Bodkin, 1990; Tacke, 1990). In addition, after a few weeks on the drug, some patients have experienced increased blood pressure and others have reported suicidal urges and agitation (Cole & Bodkin, 1990; Papp & Gorman, 1990). However, more recent studies have found fluoxetine to be no more associated with suicide than other antidepressants (Fava & Rosenbaum, 1991; Mann & Kapur, 1991).

The ***triazolopyridines,*** such as trazodone (Desyrel), are technically not tricyclics at all, but rather tetracyclics; they have mixed effects on serotonin (Preskorn & Burke, 1992). The chemical addition of an extra carbon ring is in each case claimed to reduce problematic side effects. Trazodone appeared on introduction to be a very promising drug (Moore, 1982). One study reported, however, that permanent erectile dysfunction can result from prolonged use (Lansky & Selzer, 1984).

The use of antidepressant medication has increased substantially in the United States over the past ten years. Olfson (1993) surveyed over 6000 office-based psychiatrists and found that prescriptions for antidepressant medication increased from 17.9 percent of all prescriptions in 1980 to 24.2 percent in 1985, and 30.4 percent in 1989. Most patients receiving antidepressants were women, but the rate for men was increasing, particularly for older men.

Pharmacological treatment for depression often produces dramatic results. Improvement in response to antidepressant medication is in sharp contrast to the effects of antipsychotic medications, which apparently only suppress schizophrenic symptoms. This statement, however, must be tempered with the observation that persons suffering from severe depression, unlike people with severe schizophrenia, often respond to any treatment or even no treatment at all. However, depression is often a recurrent disorder, and so drugs have to be administered over long periods. If the drugs are discontinued when symptoms have just remitted, there is a high probability of relapse, probably because the underlying depressive episode is still present and only its symptomatic expression has been suppressed (Frank et al., 1990). Long-term administration of these drugs is often effective in prevention as well as in treatment of patients subject to recurrent episodes (Montgomery, 1994).

Over the past ten years, a great deal of research has been undertaken to determine how drugs operate to alleviate depression (McNeal & Cimbolic, 1986), and which treatment or combination of treatments is appropriate for patients who are depressed (Hollon & Beck, 1986, 1994; Klerman et al., 1994). Hollon and Beck (1994) conclude that at present evidence suggests only a very modest superiority of combined treatment over cognitive or drug treatment alone. Moreover, little progress has been made in identifying patient characteristics or other clinical factors that relate to success by a given treatment method. In one nationwide study on psychological and pharmacological treatment for depression, Keller and colleagues (1986) found that there were no consistent patient characteristics related to whether a person received psychotherapy or medications for depression. More recently, Hollon and Beck (1994) also concluded that there are still no clear indications that patients with particular characteristics respond better to medication as opposed to cognitive therapy.

Overall, the use of antidepressant medication in the treatment of depressive episodes has shown considerable short-term effectiveness in spite of our lack of specific understanding of how it works and with what type of patient particular treatments are best suited. Nevertheless, a minority of severely depressed patients respond to neither type of antidepressant compound, in which case alternative modes of intervention, such as ECT, may be tried.

In addition to their usefulness in treating depression, the antidepressant drugs are also widely used in the treatment of various other disorders. For example, as discussed in Chapter 5, some of the tricyclic antidepressants (especially imipramine and clomipramine) are useful in the treatment of panic disorder (McNally, 1994; Wolfe & Maser, 1994). However, some people with panic disorder are greatly bothered by the side effects of these drugs (which create some of the symptoms panic patients are hypersensitive to) and so they quickly discontinue the medication. In the past five years a number of studies have suggested fluvoxamine, a unicyclic rather than tricyclic antidepressant, is highly promising in the treatment of panic disorder (McNally, 1994).

In addition, several antidepressant drugs are used in the treatment of obsessive-compulsive disorder (see Chapter 5). Clomipramine (a tricyclic antidepressant that has greater effects on serotonin activity than do other tricyclics) has generally been considered to be the drug treatment of choice for obsessive-compulsive disorder. However, drugs from the SSRI category (such as Prozac) also show considerable promise and have fewer troublesome side effects than does clomipramine (DeVeaugh-Geiss, 1991; Riggs & Foa, 1993).

Antidepressants have also been used effectively in the treatment of generalized anxiety disorder (Barlow, 1988; Rickels et al., 1993). Moreover, the monoamine oxidase inhibitors have been shown to be effective in the treatment of social phobia (Liebowitz et al., 1992).

Finally, antidepressant drugs are also widely used in the treatment of bulimia. Many, but not all, studies have shown that the tricyclics are useful in reducing binge-eating, relative to placebo (Mitchell & Zwann, 1993). In addition, Prozac has recently shown promising results in the treatment of bulimia, although more studies need to be done before a clear picture of its usefulness emerges.

**Antianxiety Drugs** If it is true, as some have observed, that ours is the age of anxiety, it is certainly no less true that ours is also the age of the search for anxiety reducers. Millions of prescription medications alleged to contain anxiety- and tension-relieving substances are consumed daily by the American public. In addition, Americans use other methods to reduce their anxiety—ranging from biofeedback to the practice of ancient Eastern religious rituals—that promise to relieve "uptight" feelings. The nonprescription drug market, which includes alcoholic beverages, marijuana, and decidedly more problematic substances, has had an unprecedented growth rate since the 1960s—much of it presumably due to the same widespread wish for anxiety relief.

Besides the barbiturates (see Chapter 10), which are seldom used in treatment today because they have high addictive potential and a low margin of dosage safety, two additional classes of prescription **antianxiety drugs** (minor tranquilizers) have gained widespread acceptance in recent years. One of these, the propanediols (mostly meprobamate compounds), seems to operate mainly through the reduction of muscular tension, which in turn is experienced by a patient as calming and emotionally soothing. Meprobamate drugs are marketed under the trade names Miltown and Equanil.

The other class of antianxiety drugs is the benzodiazepines. Until recently, their use in this country was increasing at an alarming rate; however, thanks to effective public warnings about the addictive potential of these drugs, this trend is now leveling off (see HIGHLIGHT 16.2). Under this rubric are included chlordiazepoxide (Librium), diazepam (Valium), oxazepam (Serax), clorazepate (Tranxene), flurazepam (Dalmane), and alprazolam (Xanax). In experimental studies on animals, the most striking effect of these drugs has been the recurrence of behavior previously inhibited by conditioned fears, without serious impairment in overall behavioral efficiency. Benzodiazepines, in other words, somehow selectively diminish generalized anxiety yet leave adaptive behaviors largely intact. They are thus far superior to many other types of anxiety-reducing drugs, which tend to produce widespread negative effects on adaptive functioning.

Nevertheless, all of the antianxiety drugs have a basically sedative effect on an organism, and many patients treated with them complain of drowsiness

16.2

## Chemically Induced Sleep: Is It Worth the Risks?

Each year about 4 percent of the population of the United States obtain a prescription for medication to help them sleep (Mendelson, 1987). Prescriptions for the benzodiazepine class of antianxiety drugs, the most widely used sleep medications, have been estimated to exceed 70 million per year in the United States. The most common benzodiazepine prescribed specifically for this purpose is flurazepam (Dalmane). Some 8 million individuals use this general class of drug sometime during any one year, and up to 2 million people take these pills nightly for more than two months at a time. It is prescribed for many patients hospitalized for physical disease.

Reacting to this overuse of anxiety medication, the Institute of Medicine (IOM) of the National Academy of Sciences issued a report outlining the hazards of this remedy for sleeping difficulties—difficulties that in any case they found to be severely overestimated on a routine basis by the people allegedly suffering from them. Noting that the barbiturates justly deserve their reputation as dangerous drugs, the IOM report indicated that the benzodiazepines may be just as risky, and in some cases more so. For example, flurazepam, while not quite as addicting as the barbiturates, remains in the body in the form of metabolites far longer than do the barbiturates, resulting in a buildup of toxic substances in the body that may reach a critical level within a week of regular ingestion. Although flurazepam overdose is usually not in itself lethal, it may interact with other drugs, such as alcohol, to produce lethal effects. Because of these readily misunderstood characteristics, the IOM concluded that, overall, flurazepam does not diminish the number of deaths attributable to sleeping pill medication, relative to earlier types of "hypnotic" drugs, such as the barbiturates.

A particularly worrisome aspect of this problem is the fact that a certain amount of benign "insomnia" naturally accompanies advancing age. Nevertheless, elderly people receive some 39 percent of all sleeping pill prescriptions. For these individuals there is a real danger that the side effects of these drugs, such as daytime lethargy and clouding of consciousness, may be considered indicators of senile deterioration by family members and even by professional caretakers. Considering the risks involved in taking these drugs, it seems appropriate to keep in mind an observation of one of the IOM members: Losing some sleep now and then is not a life-threatening problem (Smith, 1979).

and lethargy (Kutcher et al., 1992). This has been a particular problem among schoolchildren treated with these drugs. We must also emphasize that all of these drugs have the serious potential of inducing dependence when used unwisely or in excess (Bassuk, Schoonover, & Gelenberg, 1983; Levenson, 1981). Because of their potential for producing dependence, withdrawal from these drugs can be extremely difficult and must generally be accomplished slowly over a matter of weeks or months. This is especially true of the high-potency benzodiazapine Xanax, which is widely used in the treatment of panic disorder (see Chapter 5). Moreover, relapse rates following discontinuation of these drugs is extremely high. For example, as many as 60–80 percent of panic patients relapse following discontinuation of Xanax (McNally, 1994).

Anxiety drugs' range of application is quite broad. They are used in all manner of conditions in which tension and anxiety may be significant components, including anxiety-based and psychophysiologic disorders. They are also used as supplementary treatment in certain neurological disorders to control such symptoms as convulsive seizures, but they have little place in the treatment of the psychoses. They are among the most widely prescribed drugs available to physicians, a fact that has caused concern among some leaders in the medical and psychiatric fields.

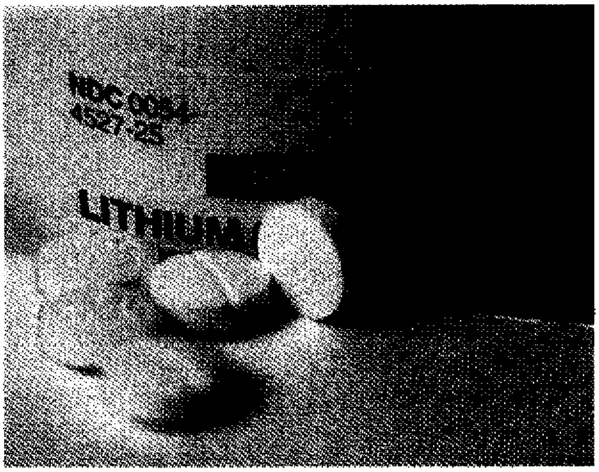
Continuing research on benzodiazepines and related compounds is turning up promising leads that will almost certainly result in important future advances in the treatment of anxiety and other conditions. It is now known that the benzodiazapines probably exert their effects through stimulating the action of GABA (*gamma aminobutyric acid*), a neurotransmitter now thought to be functionally deficient in people with generalized anxiety (Redmond, 1985). GABA ordinarily plays an important role in the way our brain inhibits anxiety in stressful situations; the benzodiazapines appear to increase GABA activity in certain parts of the brain known to be implicated in anxiety, such as the limbic system, and thereby reduce anxiety. Additionally, because these compounds also have sedative, muscle-relaxant, and anticonvulsive properties, it might be possible to differentiate specific receptors for each, and to discover variant compounds that will selectively bind to them. In fact, researchers at one large pharmaceutical company have already discovered a chemical that appears to counteract anxiety and convulsions without being a muscle relaxant or sedative. Research in this area has important implications for our basic understanding of brain processes, in addition to its obvious clinical import.

**Lithium for the Bipolar Mood Disorders** Lithium is the lightest of the metals. Its simple salts, such as lithium carbonate, were discovered—as early as 1949 by John Cade in Australia—to be effective in treating manic disorders. One of Cade's (1949) own cases will serve well as an illustration of the effects of lithium treatment:

> Mr. W. B. was a 51-year-old man who had been in a state of chronic manic excitement for five years. So obnoxious and destructive was his behavior that he had long been regarded as the most difficult patient on his ward in the hospital.
>
> He was started on treatment with a lithium compound, and within three weeks his behavior had improved to the point that transfer to the convalescent ward was deemed appropriate. He remained in the hospital for another two months, during which his behavior continued to be essentially normal. Prior to discharge, he was switched to another form of lithium salts because the one he had been taking had caused stomach upset.
>
> He was soon back at his job and living a happy and productive life. In fact, he felt so well that, contrary to instructions, he stopped taking his lithium. Thereafter he steadily became more irritable and erratic; some six months following his discharge, he had to cease work. In another five weeks he was back at the hospital in an acute manic state.
>
> Lithium therapy was immediately reestablished, with prompt positive results. In another month Mr. W. B. was pronounced ready to return to home and work, provided he would continue taking a prescribed dosage of lithium.

Some 20 years passed before lithium treatment was introduced in the United States. This delay may have been, in part, for two reasons. First, if not used at the proper dosage, lithium can be toxic, causing numerous side effects, such as delirium, convulsions, and even death. At the same time, if lithium is to have any notable therapeutic effect, it must be used in quantities within the range of potential dangerousness, which varies among different individuals. Thus, at the outset of lithium treatment, a patient's blood levels of lithium must be monitored carefully in relation to observable behavioral effects so that the minimum effective dosage can be established. For each individual, there is a relatively narrow range of effectiveness for the drug. Too little of the drug and the therapeutic effect will be negligible; too much of the drug and the effect could be lethal. In addition to these potentially dangerous side effects, lithium has some other unpleasant side effects in some patients, such as lethargy, decreased motor coordination, and gastrointestinal difficulties. Moreover, many bipolar patients seem to miss the highs and the abundance of energy associated with their hypomanic episodes, so when faced with unpleasant side effects and the loss of these highs, they may stop taking the drug.

A second possible reason for the delay in widespread lithium usage in the United States may have been the simple fact that researchers were skeptical that it was the lithium itself that was producing the beneficial results; the lithium compounds used in treatment are simple inorganic salts that have no known physiological function (Berger, 1978). Lithium, then, is a somewhat peculiar drug.



*Lithium treatment requires careful monitoring of the dosage—too much can be lethal and too little is ineffective. There is no doubt, however, that the drug has been a boon to those people who have experienced repeated bouts with mania, depression, or both throughout their adult lives.*

Its curious qualities notwithstanding, there can be no doubt at this point concerning lithium's remarkable effectiveness in promptly resolving about 70–80 percent of clearly defined manic states (Hughes & Pierattini, 1992), particularly cases in which other psychiatric disorders are not also present (Black et al., 1988). In addition, as we saw in Chapter 6, lithium is sometimes successful in relieving depression, although possibly only in those patients who are subject to both manic and depressive episodes—that is, who are bipolar in type (Bassuk et al., 1983; Berger, 1978; Segal, Yager, & Sullivan, 1976). Other research, however, suggests that there may be a subclass of unipolar depressive patients who benefit from lithium treatment (Abou-Saleh, 1992; Goodwin & Jamison, 1990).

The drug has been a boon, especially to those people who heretofore have experienced repeated bouts with mania, depression, or both throughout their adult lives. For many, these cycles can now be modulated or even prevented by regular maintenance doses of lithium—for example, by taking a single tablet each morning and evening. Psychiatry may thus have achieved its first essentially preventive treatment method—although, for some patients maintained on the drug for lengthy periods, there may be serious complications, including kidney damage (Bassuk et al., 1983) and memory and motor-speed problems (Shaw et al., 1987). There is also some recent evidence that the prevention of further attacks of mania by lithium maintenance treatment may be less reliable than was once thought. In one study, 40 percent of such patients relapsed within 1.7 years following hospital discharge (Harrow et al., 1990).

The biochemical basis of lithium's therapeutic effect is unknown. One hypothesis is that lithium, being a mineral salt, may have an effect on electrolyte balances, which may alter the properties of neurotransmission within the brain. So far, however, this connection remains largely speculative. Clearly, the riddle of exactly what occurs will be solved only by more and better research.

Recently another drug has been used with considerable success to treat bipolar disorders. The drug carbamazepine (Tegretol), used extensively as an anticonvulsant agent to control epileptic seizures, has been found effective in controlling rapidly cycling mood and reducing aggressivity in bipolar disorders (Ballenger, 1988; Gerner, 1993). On the other hand, in one study its use was somewhat disappointing for the treatment of acute mania (Lusznat, Murphy, & Nunn, 1988), which suggests that carbamazepine may be more useful in preventive treatment. Carbamazepine has been associated with significant side effects, especially neurological problems, such as an awkward gait and increased or distorted reflexes (Birkhimer, Curtis, & Jann, 1985). As such, careful monitoring of carbamezipine treatment, as with lithium use, is required.

## Drug Therapy for Children

Our discussion of the use of drugs in treating maladaptive behavior would be incomplete without some reiteration of their role in the management of childhood disturbances and disorders. We have already addressed this matter to some extent in Chapter 14. Although our society has often been too quick to label as deviant (and thus to "treat") various annoying or inconvenient behaviors in which children sometimes indulge, it is nevertheless true that some children do evidence more or less serious behavior disorders. It is also true that some of them may be helped by the judicious use of medication.

Antianxiety, antipsychotic, and antidepressant medications have all been used effectively with children who are, respectively, excessively anxious or "nervous," psychotic, or depressed (Ryan, 1992). Considerable caution must be exercised in the use of these powerful drugs with children, however, to be certain that dosage levels are within tolerable limits for a small and as yet biologically immature organism. Not only are excessive blood levels of these drugs physically dangerous, but in some instances they may produce paradoxical reversal effects—that is, a child's problem may become more severe (Bassuk et al., 1983).

Though the diagnostic terms ***hyperactivity***, ***hyperkinesis***, and ***specific learning disability*** have been used somewhat inconsistently in recent years, there appears to be a subset of highly distractable youngsters of normal but unevenly developed cognitive ability who benefit dramatically, and paradoxically, from drugs that stimulate the central nervous system (Greenhill, 1992). As we saw in Chapter 14, the most widely used of these stimulants are the amphetamines; a closely related compound known as methylphenidate (Ritalin) is also used. Recently, Whalen and colleagues (1989) found that hyperactive children treated with Ritalin were viewed more positively by other children. In certain instances, these drugs promptly terminate hyperactivity, which typically results in an increased attention span and an ability to do schoolwork (Weiss & Hechtman, 1979; Wender, Reimherr, & Wood, 1981). Normally, a child thus helped is kept on the drug until he or she reaches adolescence, when hyperactivity is thought to diminish by an as yet unknown natural process (Bassuk et al., 1983).

## A Biopsychosocial Perspective on Pharmacological Therapy

Modern psychopharmacology has brought a reduction in the severity and chronicity of many types of psychopathology, particularly the psychoses. It has helped many individuals who would otherwise require hospitalization to function in their family and community settings; it has led to the earlier discharge of those who do require hospitalization and to the greater effectiveness of after-care programs; and it has made restraints and locked wards largely obsolete. All in all, pharmacological therapy not only has outmoded more drastic forms of treatment but has led to a much more favorable hospital climate for patients and staff alike (see HIGHLIGHT 16.3 for a summary of the drugs used in psychopharmacological therapy).

Nevertheless, a number of complications and limitations arise in the use of psychotropic drugs. Aside from possible undesirable side effects, the problem of matching drug and dosage to the needs of a given individual is often a difficult one, and it is sometimes necessary to change medication in the course of treatment. In addition, the use of medications in isolation from other treatment methods is usually inappropriate and ineffective because drugs themselves do not cure disorders. As many investigators have pointed out, drugs tend to alleviate symptoms by inducing biochemical changes rather than bring an individual to grips with personal or situational factors that may be reinforcing maladaptive behaviors. Although the reduction in anxiety, depression, disturbed thinking, and other symptoms may tempt therapists to regard a patient as "recovered," it seems important to include psychotherapy in the total program if such gains are to be maintained or improved on (Beitman & Klerman, 1991). This point is underscored by the observations of relatively high relapse rates when drugs are discontinued for a variety of disorders.

On the other hand, the failure to incorporate medication into a psychotherapeutic treatment program can lead to serious problems. A recent court case, *Osherhoff* v. *Chestnut Lodge,* raised a number of issues concerning the importance of clinical diagnosis, the effectiveness of medication, and appropriate treatment intervention (Klerman, 1990). Osherhoff, a physician, was severely depressed and functioning so ineffectively that his family hospitalized him at Chestnut Lodge, an exclusively psychoanalytic treatment facility. He was treated with intensive psychoanalytic treatment, without medication, four times a week. After several months, his family became concerned over his lack of progress; he had lost 40 pounds, was experiencing severe sleep disturbance, had marked psychomotor agitation to the point that his pacing caused his feet to become swollen and blistered. The family sought a reevaluation of his case. The staff, in a case conference, decided to continue the treatment program that had been initiated. Dr. Osherhoff's condition worsened and his family had him discharged and admitted into another facility where he was treated with a combination of phenothiazines and tricyclic antidepressants. He improved markedly and was discharged in three months. Later he filed a suit claiming that Chestnut Lodge had not administered the proper treatment—drug therapy—which had caused him to lose a year of employment in his medical practice. Preliminary court arbitration indicated an initial award of damages to Dr. Osherhoff; however, the case was settled out of court before a final judgment was rendered. A number of complicated issues were involved in the case, but the finding that therapists may be liable for failing to provide medication to patients is an important and potentially disruptive new development in the field.

Thus the combination of chemical and psychological forms of therapy is fast becoming the major thrust of current research and treatment for severe psychopathology (Goldstein, 1991; Richelson, 1993). This integrative approach involves the use of psychotropic medication and psychosocial approaches, such as behavior therapy or psychoanalysis (Carpenter & Keith, 1986). It has been shown to be valuable with both adults (Ward, 1991) and children (McClellan & Wherry, 1992). The combined therapeutic approach appears to be especially useful with treatment-resistant disorders in which major mental disorders and persistent personality disorders are involved. The use of drugs can facilitate the patient's accessibility to psychotherapy and can serve to reduce noncompliant behavior in therapy. Marcus and Bradley (1990), for example, found this approach to be effective in about two-thirds of such treatment-resistant cases. The most effective uses of drugs in the treatment of psychological disorders involve drug administrations that are embedded in the context of other treatment approaches (Klerman, 1991); for example, the use of antidepressant medication along with cognitive-behavioral treatment for depression (Rush & Hollon, 1991). Overall, there is some

16.3

## Frequently Used Drugs in the Treatment of Mental and Behavioral Disorders

| Class | Generic Name | Trade Name | Used to Treat | Effects |
|---|---|---|---|---|
| Antipsychotic | | | | |
| (a) phenothiazines | chlorpromazine<br>thioridazine<br>promazine<br>trifluoperazine<br>prochlorperazine<br>perphenazine<br>fluphenazine<br>triflupromazine | Thorazine<br>Mellaril<br>Sparine<br>Stelazine<br>Compazine<br>Trilafon<br>Prolixin<br>Temaril | Psychotic (especially schizophrenia) symptoms, such as extreme agitation, delusions, and hallucinations; aggressive or violent behavior | Somewhat variable in achieving intended purpose of suppression of psychotic symptoms. Side effects, such as dry mouth, are often uncomfortable. In long-term use may produce motor disturbances, such as Parkinsonism and tardive dyskinesia. |
| (b) butyrophenone | haloperidol | Haldol | | |
| (c) thioxanthenes | thiothixine<br>chlorprothixene | Navane<br>Taractan | | |
| (d) dibenzodiazepine | clozapine | Clozaril | Schizophrenia | Suppresses psychotic thinking. Side effects include sedation, seizure, hypotension, fever, vomiting. |
| | risperidone<br>remoxipride | Risperdal | Psychotic (schizophrenic symptoms) | Like clozapine, they suppress psychotic thinking, but appear to produce fewer negative side effects and tardive dyskinesia. |
| Antidepressant | | | | |
| (a) tricyclics | imipramine<br>amitriptyline<br>nortriptyline<br>protriptyline<br>doxepin<br>trimipramine maleate<br>clomipramine | Tofranil<br>Elavil<br>Aventyl<br>Vivactil<br>Sinequan<br>Surmontil<br>Anafranil | Relatively severe depressive symptoms, especially of psychotic severity and unipolar in type; also used in treatment of panic disorder & OCD | Somewhat variable in alleviating symptoms, and noticeable effects may be delayed up to three weeks. Side effects may cause discomfort. |
| (b) monoamine oxidase (MAO) inhibitors | isocarboxazid<br>phenelzine<br>tranylcypromine | Marplan<br>Nardil<br>Parnate | Depression, panic disorder | Multiple side effects—some of them dangerous. Use of MAO inhibitors requires dietary restrictions. |
| (c) SSRIs norepinephrine/ serotonin reuptake inhibitor | fluoxetine | Prozac | Depressive symptoms, obsessive-compulsive disorder, panic disorder | Fluoxetine is effective in reducing symptoms. Effects take about 3 weeks. Safety is considered high; overdose unlikely. Side effect profile is favorable, though some nausea and insomnia have been reported. |
| | sertralin | Zoloft | Depression | Reduces depression, not considered addicting. |
| | paroxetine | Paxil | Depression | Minimal side effects. |

**16.3**

*Continued from page 620*

| Class | Generic Name | Trade Name | Used to Treat | Effects |
|---|---|---|---|---|
| (d) triazolopyridinese | | Trazodone | Depression | Less likelihood of response than TCAs. Not much used today. Minimal risk of overdose. Side effects include cognitive slowing. |
| (e) aminoketones | | Bupropion | Depression | Used with patients who have not not responded to TCAs or SSRIs. |
| Antimanic (bipolar) | lithium carbonate | Eskalith<br>Lithane<br>Lithonate<br>Lithotabs<br>Phi-Lithium | Manic episodes and some severe depressions, particularly recurrent ones or those alternating with mania | Usually effective in resolving manic episodes, but highly variable in effects on depression, probably because the latter is a less homogeneous grouping. Multiple side effects unless carefully monitored; high toxicity potential. |
| | carbamazepine | Tegretol | Manic episodes | Effective in treating bipolar disorders. Neurotoxic side effects have been noted, including unsteady gait, tremor, ataxia, and increased restlessness. |
| | valproate | Depakote | Bipolar disorder | Fewer side effects than lithium. Often used with bipolar patients who cannot take lithium. |
| Antianxiety (minor tranquilizers) | | | | |
| (a) propanediols | meprobamate | Equanil<br>Miltown | Nonpsychotic personality problems in which anxiety, tension, or panic attacks are prominent features; also used as anticonvulsants and as sleep-inducers (especially flurazepam) | Somewhat variable in achieving intended purpose of tension reduction. Used often to treat alcohol withdrawal symptoms. Side effects include drowsiness and lethargy. |
| (b) benzodiazepines | diazepam<br>chlordiazepoxide<br>flurazepam<br>oxazepam<br>clorazepate<br>alprazolam<br>prazepam | Valium<br>Librium<br>Dalmane<br>Serax<br>Tranxene<br>Xanax<br>Centrax | | |
| Stimulant | dextroamphetamine<br>amphetamine<br>methylphenidate | Dexedrine<br>Benzedrine<br>Ritalin | Hyperactivity, distractability, specific learning disabilities, and, occasionally, extreme hypoactivity | Rather unpredictable. When maximally effective, can enable otherwide uneducable children to attend regular schools. Side effects often troublesome, including recently discovered retardation of growth. |

Based on data from Bohn (1993); Dunner (1993); Goodman et al. (1985); Preskorn & Burke (1992); Tacke (1989).

reason to be optimistic about the combined use of drugs and psychosocial approaches, especially in the more severe disorders, such as schizophrenia and the major mood disorders (Beckham & Leber, 1985a; Klerman et al., 1994; Smith, Glass, & Miller, 1980).

## UNRESOLVED ISSUES

### Has Pharmacology Opened the Door to Personality Change?

The drug Prozac (fluoxetine) and others pharmacologically similar to it in primarily inhibiting the reuptake mechanism for the neurotransmitter serotonin, such as Paxil (paroxetine) and Zoloft (sertraline), are now among the drugs most proscribed by physicians. Originally considered antidepressants for use in the specific *psychiatric* treatment of relatively severe mood disorders, they are now also widely employed by many physicians, even nonpsychiatrists, to ease patients' often vague complaints of feeling unhappy. In this respect they have come to occupy a role in general medical practice not unlike that of the benzodiazepines (antianxiety agents such as Valium) during the 1970s and 1980s. The pharmacologic message appears to be that many people feel "better" when they have lots of serotonin available in the neuronal synapses of their brains.

What is the nature of this "feeling better"? Can we account for it in terms of more specific psychoactive properties of these drugs? These questions have been addressed in a thoughtful and scholarly manner by psychiatrist Peter Kramer (1993) in his popular and in certain respects startling book *Listening to Prozac*. Kramer's thesis is that Prozac does more than merely ameliorate depressive states—it actually in many instances transforms personality, usually in a very positive, self-esteem–enhancing way. He reports cases in which people claim to be functioning far better than they were before becoming depressed—literally "better than well"—or to have discovered, while on the drug, a "true" self different from and more satisfying than their previous self. In light of such remarkable effects on subjective well-being, patients are often understandably reluctant to give up the drug. That aspect, too, is reminiscent of the serious problems the overuse of benzodiazepines eventually produced.

Kramer examines several hypotheses concerning the basic psychological processes affected by Prozac, but he essentially suggests that the person on the drug experiences a diminished sensitivity to disapproval, criticism, or rejection by others. Obviously, such an effect would be of considerable benefit to those inhibited persons, not rare in the human species, who are overly dependent on maintaining uninterrupted signs of affection and approval from others, and who are miserable when they receive negative feedback. But just as obviously, there is a limit to the adaptiveness of any such imperviousness and self-containment, one that can be observed in situations where the person may appear almost entirely oblivious of others' opinions of his or her behavior. It is a bit disconcerting to contemplate living in a world in which that level of subjective social invulnerability and insensitivity toward others would be shared by everyone.

To his considerable credit, Kramer addresses forthrightly the disturbing questions raised by the availability of a prescription drug that seems not only to ameliorate disorder but in addition, for many persons, to alter their personalities, albeit mostly in ways they find pleasing. Recovery from disorder may in this context be superseded by other and quite different goals, ones with which psychiatrists or other professionals may be unprepared to deal. And Kramer is undoubtedly correct in his prediction that Prozac will prove to be only among the first of a large number of "legitimate" drugs having comparable personality-altering properties that will eventually become available. To put it another way, it seems likely that we are about to enter an era of "cosmetic psychopharmacology," conceivably one in which persons may even get to choose major aspects of their personalities, just as some now do the shapes of their noses. Such considerations give rise to the bizarre and somewhat ghastly conjecture that one day many social groups may be composed of pharmacologically synthetic personalities.

Kramer, in the authors' judgment, has performed a valuable service in alerting us to the profound problems as well as to the promise of anticipated developments in the field of psychopharmacology. Nevertheless, we think a caveat is in order. Kramer may be unduly swayed by the power of the biological model to explain and modify human personality. Time will tell whether pharmacology will have these powerful effects on human development and interpersonal behavior. We expect, however, that future research will likely demonstrate that there is far more complexity to human behavior than can be altered by the medications at hand.

## SUMMARY

Except for the development of electroconvulsive therapy (ECT) beginning in 1938, the biological approach to the treatment of mental disorders, at least on this continent and in Europe, had made little headway until about 1955. Indeed, some of the early biological treatments, such as insulin coma therapy and lobotomy, may have done more harm than good, as did many early medical treatments for purely physical diseases.

The mode of therapeutic action of ECT, which continues to be widely used, is not yet understood. There is little doubt, however, of its efficacy for certain patients, especially those suffering from severe depression. Appropriate premedication together with other modifications in technique (for example, unilateral placement of electrodes) have made this treatment relatively safe and, for the most part, have checked the serious or long-term side effects. Nevertheless, controversy about this method of treatment persists. Obviously, ECT should be used with caution and circumspection, and preferably only after less dramatic methods have been tried and have failed.

The antipsychotic compound chlorpromazine (Thorazine) became widely available in the mid-1950s. It was followed shortly by numerous other related (that is, phenothiazine class) and nonrelated antipsychotic drugs of proven effectiveness in diminishing psychotic (especially schizophrenic) symptoms. Thus was initiated a true revolution in the treatment of severe mental disorders—one that, among other things, permanently altered the environment and the function of mental hospitals. Within a short period, too, the antidepressant medications became available to help patients with severe depression. They are also widely used in the treatment of several anxiety disorders and show some promise in the treatment of bulimia. Finally, in the late 1960s (after an unaccountable delay in its introduction in this country), the antimanic drug lithium was recognized as having major therapeutic significance. With the availability of these three types of drugs, the major psychoses—for the first time in history—now came to be seen as generally and effectively treatable.

Meanwhile, antianxiety drugs (mild tranquilizers) had been developed that circumvented many of the problems of the barbiturates used earlier in combating excessive tension and anxiety. This development extended the benefit of effective drug treatment to many people who were struggling with neurotic problems or with high-stress life circumstances. The meprobamates (for example, Equanil) were the first of these new antianxiety drugs but were largely superseded by the more potent benzodiazepines (such as Valium and Xanax) for general use.

New biological treatments for mental disorders will doubtless continue to be proposed, but, as in the case of insulin therapy, many will prove undeserving of a high degree of confidence. A measure of caution is recommended concerning claims made by the proponents of newly introduced therapies.

Finally, the admittedly impressive gains in biological treatment methods may cause us to lose sight of important psychological processes that may be intrinsic to any mental disorder. In fact, some evidence shows that combinations of biologically and psychologically based approaches may be more successful than either alone, at least with some of the more severe disorders.

UNRESOLVED ISSUES ON PSYCHOTHERAPY

SUMMARY

KEY TERMS

Most of us have experienced a time or situation when we were dramatically helped by "talking things over" with a relative or friend. Or perhaps we made a drastic change in our customary behavior after a particular event led to new understanding. As the noted psychoanalyst Franz Alexander (1946) pointed out long ago, formal psychotherapy as practiced by a mental health professional shares many aspects in common with this type of familiar experience. Most therapists, like all good listeners, rely on a common repertoire of receptiveness, warmth, empathy, and a nonjudgmental approach to the problems their clients present. Most, however, also introduce into the relationship psychological interventions that are designed to promote new understandings, behaviors, or both on the client's part. The fact that these interventions are deliberately planned and systematically guided by certain theoretical preconceptions (of the kind discussed in Chapter 3) is what distinguishes professional **psychotherapy**, the treatment of mental disorders by psychological methods, from more informal helping relationships. As we will see, it is the varying nature of these theoretical concepts that largely distinguishes a given type of psychotherapy from the others available.

Psychotherapy is based on the assumption that, even in cases where physical pathology is present, an individual's perceptions, evaluations, expectations, and coping strategies also play a role in the development of the disorder and will probably need to be changed if maximum benefit is to be realized. The belief that people with psychological problems can change—can learn more adaptive ways of perceiving, evaluating, and behaving—is the conviction underlying all psychotherapy.

To achieve constructive change, a psychotherapist may attempt to (a) change maladaptive behavior patterns; (b) minimize or eliminate environmental conditions that may be causing or maintaining such behavior; (c) improve interpersonal and other competencies; (d) resolve handicapping or disabling conflicts among motives; (e) modify individuals' cognitions, their dysfunctional beliefs about themselves and their world; (f) reduce or remove distressing or disabling emotional reactions; and (g) foster a clear-cut sense of identity. All these strategies can open pathways to a more meaningful and fulfilling existence.

Achieving these changes is by no means easy. Sometimes a person's distorted view of the world and unhealthy self-concept are the end products of faulty parent-child relationships reinforced by many years of life experiences. In other instances, inadequate occupational, marital, or social adjustment requires major changes in a person's life situation, in addition to psychotherapy. Magnifying such difficulties is the fact that it is often easier to hold to one's present problematic but familiar course than to risk change and the unpredictability it entails. It would be too much to expect that a psychotherapist, even a highly skilled and experienced one, could in a short time undo an individual's entire past history and prepare him or her to cope with a difficult life situation in a fully adequate manner. Psychotherapists can offer no magical transformations of either selfhood or the realities in which people live their lives. Nevertheless, psychotherapy holds promise in even the most severe mental disorders, and indeed for certain of them may provide the only realistic hope for significant and lasting change.

It has been estimated that several hundred "therapeutic approaches" exist, ranging from psychoanalysis to Zen meditation. Indeed, the last few decades have witnessed a stream of "new therapies"—each winning avid proponents and followers for a time. The faddism in the popular literature on self-change might give the casual reader the idea that the entire field of psychotherapy is in constant flux. In reality, professional psychotherapy has shown both considerable stability over time and coherence around a few basic orientations, albeit ones that vary appreciably in the "visions" they embody of the world and of human nature (Andrews, 1989a). This chapter will explore the most widely used and accepted of these formal psychological treatment approaches.

## AN OVERVIEW OF PSYCHOLOGICAL TREATMENT

Before we turn our attention to specific psychological intervention techniques, we will attempt to gain perspective by considering more closely the individuals involved in therapy and their relationship.

### Who Receives Psychotherapy?

People who receive psychotherapy vary widely in their problems and their motivations to solve them. Perhaps the most obvious candidates for psychological treatment are individuals experiencing sudden and highly stressful situations, people who feel so overwhelmed by the crisis conditions in which they find themselves that they cannot manage on their own. These people typically feel quite vulnerable and tend to be open to psychological treatment because they are motivated to alter their present intolerable mental states. They often respond well to short-term, directive, crisis-oriented treatment (to be discussed in Chapter 18). In such situations, clients may gain considerably, in a brief time, from the outside perspective provided by their therapist.

Some people enter psychological therapy somewhat as a surprise to themselves. Perhaps they had consulted a physician for their headache or stomach pain, only to be told that there was nothing physically wrong with them. Such individuals, referred to a therapist, may at first resist the idea that their physical symptoms are emotionally based, especially if the referring physician has been brusque or unclear as to the rationale for his or her judgment. The resistant attitudes often encountered following this type of referral underscore the fact that motivation to enter treatment differs widely among psychotherapy clients. Reluctant clients may come from many sources—for example, an alcoholic whose spouse threatens "either therapy or divorce," or a suspected felon whose attorney advises that things will go better at trial if it can be announced that the suspect has "entered therapy." A substantial number of angry parents bring their children to therapists with demands that their "uncontrollable" behavior, viewed as independent of the family context, be "fixed."

Many people entering therapy have experienced long-term psychological distress and have had lengthy histories of maladjustment. They may have had interpersonal problems for some time or may have felt susceptible to low moods that are difficult for them to dispel. Chronic unhappiness and inability to feel confident and secure may finally prompt them to seek outside help. These individuals seek psychological assistance out of dissatisfaction and despair. They may enter treatment with a high degree of motivation, but, as therapy proceeds, their persistent patterns of maladaptive behavior may become resistant forces with which a therapist must contend. For example, a narcissistic client who anticipates therapist praise and admiration may become disenchanted and hostile when these are not forthcoming.

Some people who enter therapy have problems that would be considered relatively normal. That is, they appear to have achieved success, have financial stability, have generally accepting and loving families, and have accomplished many of their life goals. They enter therapy not out of personal despair or impossible interpersonal involvements, but out of a sense that they have not lived up to their own expectations and realized their own potential. These people, partly because their problems are more manageable than the problems of others, may make substantial gains in personal growth. Much of these therapeutic gains can be attributed to their high degree of motivation and personal resources. Individuals who seem to have the best prognosis for personality change, according to repeated research outcomes, have been described in terms of the so-called YAVIS pattern (Schofield, 1964)—they are Young, Attractive, Verbal, Intelligent, and Successful. Ironically, those who tend to do best in psychotherapy are those who seem objectively to need it least.

Psychotherapy, however, is not just for people who have clearly defined problems, high levels of motivation, and an ability to gain ready insight into their behavior. Psychotherapeutic interventions have been applied to a wide variety of chronic problems. Even a severely disturbed psychotic client may profit from a therapeutic relationship that takes into account his or her level of functioning and maintains therapeutic subgoals that are within the client's present capabilities.

It should be clear from this brief description of individuals in psychological therapy that there is indeed no "typical" client, nor, as we will see, is there a "model" therapy. No currently used form of therapy is applicable to all types of clients, and all of the standard therapies can document some successes. Most authorities agree that client variables, such as motivation and the seriousness of the problem, are exceedingly important to the outcome of therapy (Garfield, 1994; Lambert & Bergin, 1994; Rounsaville, Weissman, & Prusoff, 1981). As we will see, the various therapies have relatively greater success when a therapist takes the characteristics of a particular client into account in determining the treatment of choice.

## Who Provides Psychotherapeutic Services?

Members of many different professions have traditionally provided advice and counsel to individuals in emotional distress. Physicians, in addition to caring for their clients' physical problems, often become trusted advisers in emotional matters as well. In past eras, before the advent of health maintenance organizations and highly differentiated medical specialties, the family physician was called on for virtually all health questions. Even today, the medical practitioner—although he or she may have little psychological background and limited time to spend with individual clients—may be asked to give consultation in psychological matters. Many physicians are trained to recognize psychological problems that are beyond their expertise and to refer patients to psychological specialists.

Another professional group that deals extensively with people's emotional problems is the clergy. Members of the clergy are usually in intimate contact with the emotional needs and problems of their congregations. A minister, priest, or rabbi may be the first professional to encounter a person experiencing an emotional crisis. Although some clergy are trained counselors, most limit their counseling to religious matters and spiritual support and do not attempt to provide psychotherapy. Rather, like general-practice physicians, they are trained to recognize problems that require professional management and refer troubled people to mental health specialists.

The three types of mental health professionals found most often in mental health settings are clinical psychologists, psychiatrists, and psychiatric social workers (see HIGHLIGHT 17.1). The **clinical psychologist** typically has training at the undergraduate level in psychology and has a Ph.D. or Psy.D. degree in clinical psychology, with specialization in personality theory, abnormal psychology, psychological assessment, and psychotherapy. Most clinical psychologists receive broad clinical experience in assessment and psychotherapy in addition to their mental health research training. The **psychiatrist** is an M.D. who has had further training—minimally a three-year residency—in dealing with clients in a mental health setting. The medical training of psychiatrists qualifies them for administering somatic therapies, such as electroconvulsive therapy and psychotropic medication. In addition, during residency, psychiatric residents receive supervision in psychotherapy. **Psychiatric social workers** are usually trained in social science at the bachelor's level and may hold an M.S.W. or Ph.D. from a school of social work. Their graduate training usually involves courses in family evaluation, psychotherapy, and supervised field experiences.

In a clinic or hospital, as opposed to an individual practice setting, a wide range of medical, psychological, and social work procedures may be used. These range from the use of drugs to individual or group psychotherapy and to home, school, or job visits aimed at modifying adverse conditions in a client's life. Often the latter—as in helping a teacher become more understanding and supportive of a child client's needs—is as important as treatment directed toward modifying the client's personality makeup, behavior, or both.

This willingness to use a variety of procedures is reflected in the frequent use of a team approach to

17.1

## Personnel in Psychotherapy

**Professional**

*Clinical Psychologist*

Ph.D. in psychology with both research and clinical skill specialization. One-year internship in a psychiatric hospital or mental health center. Or, Psy.D. in psychology (a professional degree with more clinical than research specialization) plus one-year internship in a psychiatric hospital or mental health center.

*Counseling Psychologist*

Ph.D. in psychology plus internship in a marital- or student-counseling setting; normally, a counseling psychologist deals with adjustment problems not involving mental disorder.

*School Psychologist*

Ideally a person having doctoral training in child-clinical psychology, with additional training and experience in academic and learning problems. At present, many school systems lack the resources to maintain an adequate school psychology program.

*Psychiatrist*

M.D. degree with residency training (usually three years) in a psychiatric hospital or mental health facility.

*Psychoanalyst*

M.D. or Ph.D. degree plus intensive training in the theory and practice of psychoanalysis.

*Psychiatric Social Worker*

B.A., M.S.W., or Ph.D. degree with specialized clinical training in mental health settings.

*Psychiatric Nurse*

R.N. degree plus specialized training in the care and treatment of psychiatric clients. Nurses can attain M.A. and Ph.D. degrees in psychiatric nursing.

*Occupational Therapist*

B.S. in occupational therapy plus internship training with physically or psychologically handicapped individuals, helping them make the most of their resources.

*Pastoral Counselor*

Ministerial background plus training in psychology. Internship in mental health facility as a chaplain.

**Paraprofessional**

*Community Mental Health Worker*

Capable person with limited professional training who works under professional direction (especially crisis intervention).

*Alcohol- or Drug-Abuse Counselor*

Limited professional training but trained in the evaluation and management of alcohol- and drug-addicted people.

In both mental health clinics and hospitals, personnel from several fields may function as an interdisciplinary team—for example, a psychiatrist, a clinical psychologist, a social worker, a psychiatric nurse, and an occupational therapist may work together.

assessment and treatment, particularly in group practice and institutional settings. This approach ideally involves the coordinated efforts of medical, psychological, social work, and other mental health personnel working together as the needs of each case warrant. Also of key importance is the current practice of providing treatment facilities in the community. Instead of considering maladjustment as an individual's private misery, which in the past often required confinement in a distant mental hospital, this approach integrates family and community resources in the treatment.

## The Therapeutic Relationship

The therapeutic relationship is formed out of what both a careseeker and a caregiver bring to the therapeutic situation. The client's major contribution is his or her motivation. The humanistic tenet—that all humans are at base far more like each other than different and possess an inner drive toward mental and physical health—makes effective psychotherapy possible. Just as physical medicine, properly used, essentially frees and cooperates with the body's own healing mechanisms, an important ally for a psychotherapist is the client's own drive toward wholeness and toward the development of unrealized potentialities. Although this inner drive is often obscured in severely disturbed clients, most anxious and confused people are sufficiently discouraged with their situation to be eager to cooperate in any program that holds hope for improvement.

Motivation to change is probably the most crucial element in determining the success or failure of psychotherapy, and a wise therapist is appropriately cautious about accepting an unmotivated client. Not all prospective clients, regardless of their need for treatment, are ready for the discomfort that effective therapy may entail. Even the motivation of self-referred clients may dissipate in the face of the painful confrontations good therapy may require.

Almost as important is a client's expectation of receiving help. This expectancy is often sufficient in itself to bring about some improvement (Frank, 1978). Just as a placebo pill often lessens pain for someone who believes it will do so, a person who expects to be helped by psychotherapy is likely to be helped, almost regardless of the particular methods used by a therapist. The downside of this fact is that a therapist who appears inept, bumbling, or unconfident may compromise potential benefits even where the treatment plan is entirely appropriate for the presenting problem. Therapists are usually the first to admit that their "art" is inexact and dependent on what a client and therapist bring to the experience of treatment.

To the art of therapy, a therapist brings a variety of professional skills and methods intended to help individuals see themselves and their situations more objectively—that is, to gain a different perspective. Insight and new perspective, however, are only a start and not usually enough alone to bring about the necessary changes in behavior. Besides helping provide a new perspective, most therapy situations also offer a client a protected setting in which he or she is helped to practice new ways of feeling and acting, gradually developing both the courage and the ability to take responsibility for acting in more effective and satisfying ways.

To bring about such changes, an effective psychotherapist must interact with a client in such a manner as to discourage old and dysfunctional behavior patterns and induce new and more functional ones in their place. Because clients will present varying challenges in this regard, the therapist must be flexible enough to deploy a variety of interactive styles. For example, a therapist who inadvertently but unfailingly takes charge in finding solutions for clients' problems will have considerable difficulty in working with people presenting serious difficulties in the area of inhibited autonomy, as in dependent personality disorder. To at least some extent, effective therapy depends on a good match between client and therapist (Talley, Strupp, & Morey, 1990). Hence, a therapist's own personality is necessarily a factor of some importance in determining therapeutic outcomes, quite aside from his or her background and training or the particular formal treatment plan adopted (Beutler, Machado, & Neufeldt, 1994; Lambert, 1989).

Despite general agreement among psychotherapists on these aspects of the client-therapist relationship, professionals can and do differ in their diagnoses and treatments of psychological disorders. This statement should not be surprising, of course. Even in the treatment of physical disorders, we sometimes find that physicians disagree. In psychopathology, such disagreements are even more common. The differing viewpoints on human motivation and behavior

*Effective psychotherapy is a "working alliance," requiring a good therapeutic relationship.*

outlined in Chapter 3 lead to quite different appraisals of exactly what "the problem" is and how a person should be helped to overcome it. The next section provides a brief perspective on the several types of therapy available and on how they are able to coexist and complement one another, despite their evident differences.

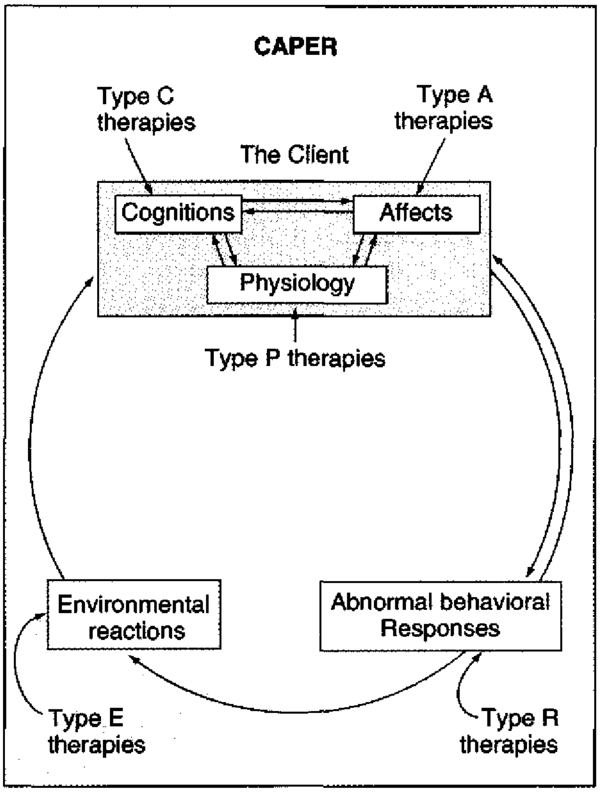
## A Perspective on Therapeutic Pluralism

Mastering the sometimes bewildering array of available therapeutic techniques is difficult at best. One way of attempting to do so is to reduce the domain to five general types or classes of therapy interventions according to the principal client subsystem targeted for therapeutic attention: Cognition, Affect, Physiology, Environment, and Behavioral Response (CAPER). The CAPER framework (which is illustrated in HIGHLIGHT 17.2) is our own attempt to summarize this complex domain; we hope it will be of value to you by providing a convenient orienting framework.

According to this scheme, biological therapies, reviewed in the preceding chapter, would be considered Type P therapies because they involve direct at-

17.2

### CAPER: Classes of Therapeutic Strategies According to the Primary Target for Change



The accompanying figure depicts in schematic fashion the situation of a typical psychotherapy client, who is conceived here as a conglomerate of mutually influencing cognitions, affects, and physiologic states. A principal output of this system is overt behavioral responding, some of which is maladaptive or abnormal. The impact of this abnormal behavior on the environment (chiefly the social or interpersonal environment) generates information-laden reactions that are in turn registered by the client's cognition-affect-physiologic system. (The reverse direction arrow from behavior to client acknowledges the scattered evidence that this type of influence also occurs.) In the case of persisting behavioral abnormality, we assume that much of the information gleaned from the reacting environment is such as to "confirm," or at least not disconfirm, client cognitions, affects, and associated physiologic states; were it otherwise, we would anticipate a restructuring of the system and, typically, a termination of the abnormal behavior. Therapy is thus a matter of interrupting the self-sustaining loop supporting the behavioral abnormality. Seen in this light, therapy might conceivably be effective by inducing positive change in any one of the component nodes of the loop. Differing types of therapy, here organized into Types C (cognitive), A (affective), P (physiologic), E (environmental), and R (behavioral response), do in fact tend to focus efforts at therapeutic change on one or another of these nodes, as further described in the text.

tempts to alter a client's Physiology in the hope that such change will result in beneficial alteration in other systems as well. Operant conditioning therapies, on the other hand, would practically always be of Type R because of their focus on bringing about direct changes in maladaptive behavioral Responding through the manipulation of reinforcement contingencies. Type C, A, and E therapies involve, in turn, interventions focused respectively on maladaptive client Cognitions and Affects, and on pathology-sustaining reactions in the client's Environment. Therapists have at least these choices in deciding where their efforts should primarily be directed.

As we will see, and indeed as might be anticipated, not all therapies fit neatly into one or another of the types. Usually, however, a dominant therapeutic target is discernible that makes such classification feasible. Of course, such a classification scheme becomes irrelevant for truly comprehensive programs of therapy, such as the so-called multimodal, but these seem (unfortunately, we think) the exception rather than the rule in clinical practice. Although most therapists describe themselves as "eclectic" in orientation, most favor particular approaches, and some commentators (e.g., Patterson, 1989) doubt even the possibility of "integration." We will point out in the following sections what seem to be the dominant types (C, A, P, E, or R) of the several kinds of psychotherapy to be described.

Before proceeding, one other aspect of HIGHLIGHT 17.2 deserves mention—namely, its form as a continuous loop. We think this form reflects the reality of the relationships among (a) the client, conceived as a system of integrated cognitions, affects, and physiologic reactions or states; (b) his or her abnormal behavioral response output, assumed to be a product of (a); and (c) the reactions of the person's environment to that output, in turn "feeding back" to the person's cognition-affect-physiologic system information that tends to support or confirm the "contents" of the system. This aspect of our model is neither idiosyncratic nor new, and developments of certain of its facets now commonly appear in the professional literature (e.g., Andrews, 1989b; Safran, 1990a, 1990b; Strupp, 1993; Wachtel, 1993).

The model has two important and related implications for therapy. First, the question of causal primacy, of how the abnormal behavior got started, is not especially relevant; once in operation, the loop, theoretically, is self-sustaining. Second, it should be possible to effect a positive overall outcome by fostering adaptive change in any pertinent component of the loop, whether physiology, cognitions, affects, overt responses, or even the reacting environment. That is, effective therapy consists of interrupting this pathology-sustaining loop. In our view, then, most competing types of therapy can realistically claim their share of successes (Smith et al., 1980) precisely because they induce adaptive change in one or another of these critical system components, thereby (perhaps unwittingly) positively affecting the whole (see Stiles, Shapiro, & Elliott, 1986).

Maintaining this overview as a backdrop, we now will consider several forms of psychotherapy that have evolved over the century since Sigmund Freud's first such effort. In fact, we will begin with that tradition.

## PSYCHODYNAMIC THERAPY

**Psychodynamic therapy** is a psychological treatment approach that focuses on individual personality dynamics from a psychoanalytic perspective (see Chapter 3). It is practiced in two basic forms: (a) classical psychoanalysis, and (b) psychoanalytically oriented psychotherapy. Therapists who practice either form are often referred to as psychoanalysts or, simply, analysts. As developed by Freud and his immediate followers, classical psychoanalysis is an intensive, long-term procedure for uncovering repressed memories, thoughts, fears, and conflicts presumably stemming from problems in early psychosexual development—and helping individuals come to terms with them in light of the realities of adult life. It is thought that gaining insight into such repressed material frees individuals from the need to keep squandering their energies on repression and other defense mechanisms. Instead, they can bring their personality resources to bear on consciously resolving the anxieties that prompted the repression in the first place. Freed from this load of threatening material and from the effort of keeping it out of consciousness (so the theory states), they can turn their energies to better personality integration and more effective living.

In psychoanalytically oriented psychotherapy the treatment and the ideas guiding it may depart substantially from the principles and procedures laid out by orthodox Freudian theory, yet the therapy is still based on psychoanalytic concepts. For example, many psychoanalytically oriented therapists schedule less frequent sessions and use techniques such as active challenging of defenses in an effort to shorten total treatment time. We will examine first Freud's original treatment methods, in part because of their historical significance and enormous influence; then we will look briefly at some of the contemporary modifications of psychoanalytic therapy.

## Freudian Psychoanalysis

Psychoanalysis is a system of therapy that evolved over a period of years during Freud's long career. It is not an easy system of therapy to describe, and the problem is complicated by the fact that many people have inaccurate conceptions of it based on cartoons and other forms of caricature. The best way to begin our discussion is to describe the four basic techniques of this form of therapy: free association, analysis of dreams, analysis of resistance, and analysis of transference. Then we will note some of the most important changes that have taken place in psychoanalytic therapy since Freud's time.

**Free Association** As we saw in Chapter 2, Freud used hypnosis in his early work to free repressed thoughts from his clients' unconscious (see HIGHLIGHT 17.3). Later, he stopped using hypnosis in favor of a more direct method of gaining access to a person's hidden thoughts and fears—**free association.**

The basic rule of free association is that an individual must say whatever comes into his or her mind, regardless of how personal, painful, or seemingly irrelevant it may be. Usually a client sits comfortably in a chair or lies in a relaxed position on a couch and gives a running account of all the thoughts, feelings, and desires that come to mind as one idea leads to another. The therapist usually takes a position behind the client so as not to in any way distract or disrupt the free flow of associations.

Although such a running account of whatever comes into one's head may seem random, Freud did not view it as such; rather, he believed that associations are determined like other events. As we have seen, he also thought that the conscious represents a relatively small part of the mind, while the preconscious and unconscious are the much larger portions. The purpose of free association is to explore thoroughly the contents of the preconscious, that part of mind considered subject to conscious attention but largely ignored. The preconscious contents, it is thought, contain derivatives of repressed unconscious material, which if properly "interpreted" can lead to an uncovering of the latter. Analytic interpretation involves a therapist's tying together a client's often disconnected ideas, beliefs, actions, and so forth into a meaningful explanation to help the client gain insight into the relationship between his or her maladaptive behavior and the repressed (unconscious) events and fantasies that drive it.

**Analysis of Dreams** Another important, related procedure for uncovering unconscious material is dream analysis. When a person is asleep, repressive defenses are said to be lowered and forbidden desires and feelings may find an outlet in dreams. For this reason, dreams have been referred to as the "royal road to the unconscious." Some motives, however, are so unacceptable to an individual that even in dreams they are not revealed openly but are expressed in disguised or symbolic form. Thus a dream has two kinds of content: **manifest content,** which is the dream as it appears to the dreamer, and **latent content,** composed of the actual motives that are seeking expression but are so painful or unacceptable that they are disguised.

It is a therapist's task to uncover these disguised meanings by studying the images that appear in the manifest content of a client's dream and his or her preconscious associations to them. For example, a client's dream of being engulfed in a tidal wave may be interpreted by a therapist as indicating that the client feels in danger of being overwhelmed by inadequately repressed fears and hostilities.

**Analysis of Resistance** During the process of free association or of associating to dreams, an individual may evidence **resistance**—an unwillingness or inability to talk about certain thoughts, motives, or experiences (Strean, 1985). For example, a client may be talking about an important childhood experience and then suddenly switch topics, perhaps stating, "It really isn't that important," or "It is too absurd to discuss." Resistance may also be evidenced by the client's giving a too-glib interpretation of some association, or coming late to an appointment, or even "forgetting" an appointment altogether. Because resistance prevents painful and threatening material from entering awareness, its sources must be sought if an individual is to face the problem and learn to deal with it in a realistic manner.

**Analysis of Transference** As client and therapist interact, the relationship between them may become complex and emotionally involved. Often people carry over and apply to their therapist attitudes and feelings that they had in their relations with a parent or other person close to them in the past, a process known as **transference.** Thus clients may react to their analyst as they did to that earlier person and feel the same love, hostility, or rejection that they felt long ago. If the analyst is operating according to the prescribed role of maintaining an impersonal stance of detached attention, the often affect-laden reactions of the client can be interpreted, it is held, as a type of projection—inappropriate to the present

17.3

## The Use of Hypnosis in Therapy

Hypnosis was known among the ancient Egyptians and other early peoples, but its modern use in psychotherapy dates only from the time of Mesmer, as we saw in Chapter 2. Since that time, there have been periodic fluctuations in the popularity of hypnosis in psychotherapy, and differing viewpoints have arisen concerning the exact nature of hypnotic phenomena. In general, hypnosis may be defined as an altered state of consciousness involving extreme suggestibility. Hypnotic induction procedures are designed to bring about a heightened state of selective attention in which a subject "tunes out" irrelevant stimuli and concentrates solely on the hypnotist's suggestions. The induction of hypnosis and its therapeutic uses are briefly outlined here:

1. *Induction of hypnosis.* Hypnosis may be induced by a variety of techniques, most of which involve the following factors: (a) enlisting a subject's cooperation and allaying any fears of hypnosis; (b) having the subject assume a comfortable position and relax completely; (c) narrowing and focusing the subject's attention, perhaps by having him or her gaze on some bright object; and (d) directing the subject's activities by means of suggestions. The latter often involves establishing the assumption that normal bodily reactions have in fact come about at the direction of the hypnotist. For example, a subject may be directed to gaze upward toward an object and then be told, "Your eyelids are starting to feel heavy." This is a normal reaction to the strain of looking upward, but the subject thinks it is caused by the hypnotist; thus the way is paved to accept further suggestions.

2. *Recall of buried memories.* Traumatic experiences that have been repressed from consciousness may be recovered under hypnosis. This technique was used in treating combat-exhaustion cases during World War II. Under hypnosis, an amnesic soldier could relive his battle experience, thus discharging the emotional tensions associated with it and permitting the experience to be assimilated into his self-structure. Civilian reactions involving amnesia may be similarly handled. As was noted in Chapter 7, the use of hypnosis to recover memories of alleged childhood abuse has come under fire in recent years as evidence has mounted that some overzealous hypnotist-therapists have encouraged the "recall" of false memories.

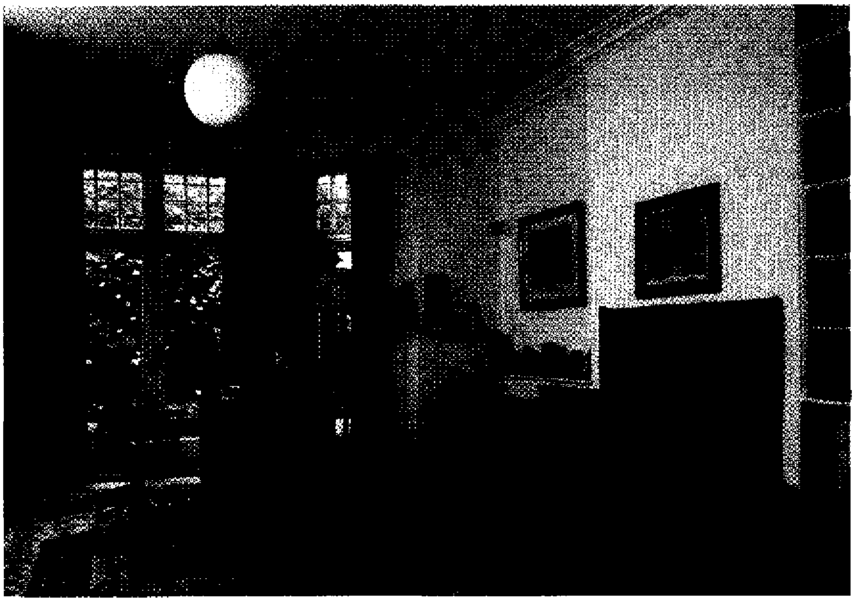
3. *Age regression.* Closely related to memory recall is hypnotic age regression. A hypnotized woman, for example, may be told that she is now a six-year-old child again and will subsequently act, talk, and think much as she did at the age of six. Regression to the age just preceding the onset of phobias often brings to light the traumatic experiences that precipitated them. Here again, reliving the traumatic experience may desensitize a subject to it. Age regression below the point at which an individual acquired verbally mediated memory is not possible. Contrary to what some claim, age regression to "past lives" is also not possible.

4. *Dream induction.* Dreams can be induced through hypnosis, although some investigators consider hypnotic dreams to more nearly resemble fantasies than nocturnal dreams. In any event, hypnotic dreams may be used to explore intrapsychic conflicts along the lines of dream analysis worked out by Freud. Perhaps the particular value of such dreams is that a therapist can suggest the theme about which the hypnotic dream should center, using it much like a projective technique in exploring an individual's inner conflicts.

5. *Posthypnotic suggestion.* One of the hypnotic phenomena most widely used in psychotherapy is posthypnotic suggestion. In this technique, a therapist makes suggestions to a subject during the hypnotic state for behavior to be carried out later in the waking state, with the subject remaining unaware of the source of the behavior. For example, a subject may be told that he or she will no longer have a desire to smoke upon coming out of the hypnotic state. Although such suggestions do carry over into the waking state, their duration is usually short. That is, the individual may again experience a desire to smoke in a few hours or a few days. This time factor can be partially compensated for, however, by regular reinforcement of the posthypnotic suggestion in booster sessions.

Some investigators attribute the altered state of consciousness in hypnosis to the subject's strong motivation to meet the demand characteristics of the situation. Barber (1969), for example, has shown that many of the behaviors induced under hypnosis can be replicated in nonhypnotized subjects simply by giving instructions which they are strongly motivated to follow. The preponderance of research evidence, however, indicates that behavior induced in hypnotized subjects does differ significantly from that evidenced during simulated hypnosis or role enactment (Diamond, 1974; Fromm & Shor, 1972; Hilgard, 1973, 1974; Miller & Springer, 1974; Nace, Orne, & Hammer, 1974; Rhue, Lynn, & Kirsch, 1993). For example, a number of investigators have offered dramatic evidence that the pain response can be brought almost completely under hypnotic control in many subjects, permitting a degree of pain reduction well beyond that produced in nonhypnotized subjects.

Such drugs as sodium pentothal can be used to produce phenomena similar to those manifested in a hypnotic trance. This form of biological therapy is referred to as narcoanalysis or narcosynthesis. Sodium pentothal has been used to treat severe cases of combat exhaustion involving amnesia.



*Freud's office. Freud had his patients use the couch during psychoanalysis, both to enhance relaxation and to avoid distracting eye contact.*

situation, yet highly revealing of central issues in the client's life.

By recognizing the transference relationship, a therapist may provide the client with insight as to the meaning of his or her reactions in the present context, and may also introduce a corrective emotional experience by refusing as it were to engage the person on the basis of his or her unwarranted assumptions about the nature of the therapeutic relationship. If the client expects rejection and criticism, for example, the therapist is careful to maintain a neutral manner. In this way it may be possible for the individual to "work through" the conflict in feelings about the real parent or perhaps to overcome feelings of hostility and self-devaluation that stemmed from the earlier parental rejection. In essence, the pathogenic effects of an undesirable early relationship are counteracted by working through a similar emotional conflict in a therapeutic setting. Because a person's reliving of a pathogenic past relationship in a sense recreates the neurosis in real life, this experience is often referred to as a *transference neurosis.*

It is not possible here to consider at length the complexities of transference relationships, but we can stress that a client's attitudes toward his or her therapist usually do not follow such simple patterns as our example suggests. Often the client is ambivalent—distrusting the therapist and feeling hostile toward him or her as a symbol of authority, but at the same time seeking acceptance and love. In addition, the problems of transference are not confined to the client, for the therapist may also have a mixture of feelings toward the client. This phenomenon is known as **counter-transference** and must be recognized and handled properly by the therapist. For this reason, it is considered important that therapists have a thorough understanding of their own motives, conflicts, and "weak spots"; in fact, all psychoanalysts themselves undergo psychoanalysis before they begin independent practice.

The resolution of the transference neurosis is said to be the key element in effecting a psychoanalytic "cure." Such resolution can only occur if an analyst successfully avoids the pitfalls of counter-transference. That is, the analyst must focus on control of the "environmental" (i.e., his or her own) reaction to a client's behavior. Accordingly, we consider psychoanalysis and psychoanalytically oriented therapy to be primarily Type E in character.

## Psychodynamic Therapy Since Freud

The original version of psychoanalysis is practiced only rarely today. Arduous and expensive in time, money, and emotional commitment, it normally entails three to five one-hour sessions per week, and it may take several years until both analyst and client are satisfied that all major issues in the client's life have been satisfactorily resolved. In light of these heavy demands, most psychoanalytic/psychodynamic therapists have worked out modifications in procedure designed to shorten the time and expense required. Mann (1973), for example, has described an approach that follows psychodynamic methods but is confined to a 12-session treatment course aimed at symptom relief. Other psychoanalytically oriented approaches have recently been reviewed by Henry and colleagues (1994).

Probably the most extensive program of short-term psychodynamic therapy, one involving a strong research/evaluation component, is that of Strupp and colleagues at Vanderbilt University (Strupp, 1981, 1993; Strupp & Binder, 1984). This therapy, known as time-limited dynamic psychotherapy, goes beyond symptom relief and aims for lasting modification of an individual's personality by applying modified psychodynamic principles in therapy that lasts for 25–30 sessions. The modifications introduced here have a substantial interpersonal focus, in keeping with a clear trend of contemporary psychodynamic thinking.

The interpersonal focus of much modern psychodynamic therapy, including approaches deriving from the object-relations focus of contemporary psychoanalysis (Cashdan, 1988), has roots in England as well as the United States. (As was seen in Chapter 3, a major American figure in this development was Harry Stack Sullivan.) Most generally these procedures make central and build on one of Freud's most brilliant insights—that a person's current relationship to the social environment is determined significantly by persistent, unconscious memory traces, or schemas, laid down in his or her earliest relationships with significant others. While the classical analysts have tended to see these script-like recreations of the past as played out mainly under the special circumstances of transference in psychoanalytic treatment, interpersonal therapists hold that these precedents are always operative in a person's relationship to all others, not just to his or her therapist.

Often a client's schemas about what people are like and what one may expect from them are not only erroneous in terms of present circumstances but also quite destructive in their effects on current interpersonal functioning. Sometimes they lead to repeating the same mistakes and the same poor choices in relationships time and time again, and to the maintenance of highly dysfunctional self-fulfilling prophecies (Carson, 1982; Wachtel, 1993). Interpersonal and object-relations therapists tend to ignore the sorts of libidinal drives and psychic structures Freudians emphasize and tend instead to focus their efforts on correcting their clients' distorted views of the interpersonal environment. In this respect the approach is indistinguishable from certain aspects of cognitive therapy, although interpersonalists tend more to use their own relationship to clients as the laboratory for the latter's acquisition of new and more functional cognitive schemas.

An important variant of interpersonally based psychotherapy, interpersonal psychotherapy (IPT) for depression, has been developed in recent years by a group of therapist-researchers from Harvard and Yale. As will be seen below, it was featured prominently in a national study comparing various treatments for depression, one we will consider in greater detail in discussing outcome research.

Other differences in contemporary psychodynamic treatment have also evolved. For example, today's analytic therapists tend to place more emphasis on current ego functioning and see the ego as a developing and controlling agent in an individual's life, not merely an uncertain regulator of uncompromising drives. Thus an individual is seen as more capable of being in control and less dominated by early repressed sexuality than in traditional analysis. Although childhood events are still viewed as important formative experiences, most modern psychodynamic therapists also place more emphasis on clients' current life situations and less on their childhood experiences. Many important contemporary situations are, of course, ones involving other people, thus making for a certain rapprochement with other trends already noted.

## Evaluation of Psychodynamic Therapy

Despite such modifications, psychodynamic therapy is still commonly criticized for being relatively time-consuming and expensive; for being based on a questionable, stultified, and sometimes cultlike approach to human nature; for neglecting a client's immediate problems in the search for unconscious conflicts in the remote past; and for inadequate proof of general effectiveness. Concerning the last of these, we actually have relatively little solid research data on the efficacy of either the classical or the newer variants of psychodynamic therapy. With notable exceptions, such as the Vanderbilt psychotherapy project previously noted (see Strupp & Binder, 1984; Strupp, 1993), rigorous research on outcomes has not been a strength of the psychodynamic therapies.

The criticisms noted above have been mostly directed at classical psychoanalysis, and in our judgment are merited to a degree. With a few exceptions, analysts have been less than eager to subject their treatment outcomes to rigorous scrutiny, and when they have done so (see Smith et al., 1980; Wallerstein, 1989) the results have not been especially impressive, at least when considered in relation to the usually optimistic goals and considerable investments involved. Because it expects a person to achieve insight and major personality change, psychoanalysis is also limited in its applicability. For example, it appears best suited for people who are average or above in intelligence and economically well off, and who do not suffer from severe psychopathology. In the present era of concern for "cost-effectiveness" and "accountability" in the mental therapy field, classical psychoanalysis appears increasingly to be a therapy for the elite.

Nevertheless, many people do feel that they have profited from psychoanalytic therapy—particularly in terms of greater self-understanding, relief from inner conflict and anxiety, and improved interpersonal relationships. Psychoanalytically oriented psychotherapy remains the treatment of choice for many individuals who are seeking extensive self-evaluation or insight into themselves. Even some behavior therapists, when seeking treatment for themselves, have selected this approach over behavioral methods (Gochman, Allgood, & Geer, 1982), which surely says something about the value they place on it.

## BEHAVIOR THERAPY

Although the use of conditioning techniques in therapy has a long history, it was not until the 1960s that **behavior therapy,** the use of therapeutic procedures based (as originally formulated) on the principles of classical and operant conditioning, really came into its own. The major reason for the long delay was the dominant position of psychoanalysis in the field. In recent years, however, the therapeutic potential of behavior therapy techniques has been strikingly demonstrated in dealing with a wide variety of maladaptive behaviors, and literally thousands of research publications have dealt with the systematic application of behavior-change principles to modify maladaptive behavior.

In the behavioral perspective, as we saw in Chapter 3, a maladjusted person (unless suffering from brain pathology) is seen as differing from other people only in (a) having failed to acquire competencies needed for coping with the problems of living, (b) having learned faulty reactions or coping patterns that are being maintained by some kind of reinforcement, or (c) both. Thus a behavior therapist specifies in advance the precise maladaptive behaviors to be modified and the adaptive behaviors to be achieved, as well as the specific learning principles or procedures to be used in producing the desired results.

Instead of exploring past traumatic events or inner conflicts, behavior therapists attempt to modify problem behaviors directly by extinguishing or counter-conditioning maladaptive reactions, such as anxiety, or by manipulating environmental contingencies—that is, by the use of reward, suspension of reward, or, occasionally, punishment to shape overt actions. Indeed, for the strict behaviorist, "personality" does not exist except in the form of a collection of modifiable habits. Behavior therapy techniques seem especially effective in altering maladaptive behavior when a reinforcement is administered contiguous with a desired response, and when a person knows what is expected and why the reinforcement is given. The ultimate goal, of course, is not only to achieve the desired responses but to bring them under the control and self-monitoring of the individual.

We have cited many examples of the application of behavior therapy in earlier chapters. In this section, we will elaborate briefly on the key techniques of behavior therapy.

### Extinction

Because learned behavior patterns tend to weaken and disappear over time if they are not reinforced, often the simplest way to eliminate a maladaptive pattern is to remove the reinforcement for it. This is especially true in situations where maladaptive behavior has been reinforced unknowingly by others, an extremely common occurrence as illustrated by this case:

> Billy, a 6-year-old first grader, was brought to a psychological clinic by his parents because he "hated school" and his teacher had told them that his showing-off behavior was disrupting the class and making him unpopular. It became apparent in observing Billy and his parents during the initial interview that both his mother and father were noncritical and approving of everything he did. After further assessment, a three-phase program of therapy was undertaken: (a) the parents were helped to discriminate between showing-off behavior and appropriate behavior on Billy's part; (b) the parents were instructed to show a loss of interest and attention when Billy engaged in showing-off behavior while continuing to show their approval of appropriate behavior; and (c) Billy's teacher was instructed to ignore Billy, insofar as it was feasible, when he engaged in showing-off behavior, and to devote her attention at those times to children who were behaving more appropriately.
>
> Although Billy's showing-off behavior in class increased during the first few days of this behav-

ior therapy program, it diminished markedly thereafter when it was no longer reinforced by his parents and teacher. As his maladaptive behavior diminished, he was better accepted by his classmates, which, in turn, helped reinforce more appropriate behavior patterns and changed his negative attitude toward school.

Billy's therapy, thus, was basically of the Type R sort (direct modification of maladaptive responses), as mediated by a Type E strategy—changing the environmental reaction (of his parents and teacher) to the behavior.

Two techniques that rely on the principle of extinction are ***implosive therapy*** and ***flooding***. Both focus on extinguishing the conditioned fear and accompanying avoidance behavior induced by anxiety-arousing stimuli and can thus be used to treat anxiety disorders. Accordingly, they are primarily Type A therapies in focusing on the modification of the affect of anxiety. The techniques are roughly similar, except that **implosive therapy,** as that term is now generally used, involves having a client imagine (in vitro) anxiety-arousing situations, usually with much coaching and modeling provided by a therapist; **flooding,** on the other hand, involves inducing a client to undergo repeated exposures to his or her real-life (in vivo) anxiety-arousing situations, usually again with the therapist in an active coaching role.

In implosion, clients are asked to imagine and relive aversive scenes associated with their anxiety. However, instead of trying to banish anxiety from the treatment sessions, as in the older technique of systematic desensitization, a therapist deliberately attempts to elicit a massive "implosion" of anxiety. This is somewhat reminiscent of psychodynamic approaches because it often deals with past trauma and conceptualizes anxiety as a response to internal threat, though most traditional analysts would doubtless strongly disapprove of the procedure. With repeated exposure in a "safe" setting, the stimulus loses its power to elicit anxiety (classical extinction), and the derivative avoidance behavior thus becomes nonfunctional and hence unreinforced by anxiety reduction (operant extinction). Hypnosis or drugs may be used to enhance vivid imagery under implosive therapy.

In a report of an actual case, Stampfl (1975) described a young woman who could not swim and was terrified of water—particularly of sinking under the water. Although she knew it was irrational, she was so terrified of water "that she wore a life preserver when she took a bath" (p. 66). She was instructed by the therapist to imagine in minute detail taking a bath without a life preserver in a "bottomless" tub, and slipping under the water. Initially, the client showed intense anxiety, and the scene was repeated over and over. In addition, she was given a "homework" assignment in which she was asked to imagine herself drowning. Eventually, after imagining the worst and finding that nothing happened, her anxiety diminished. After the fourteenth therapy session, she was able to take baths without feelings of anxiety; the maladaptive behavior had been effectively extinguished.

*Flooding is a technique that involves placing an individual in a real-life, anxiety-arousing situation with the goal of extinguishing the conditioned avoidance of an anxiety-provoking stimulus. For example, a client with a fear of heights may be taken to the top of a tall building to demonstrate that the feared consequences do not occur.*

Imaginal procedures have some limitations, an obvious one being that not all persons are capable of vividly imagining the required scenes. In a study of clients with agoraphobia, Emmelkamp and Wessels (1975) concluded that prolonged exposure in vivo plainly proved superior to simple reliance on the imagination, and in recent years the flooding procedure seems to have gained a definite ascendancy over that of in vitro imagining wherever it is possible to identify in concrete terms those situations evoking anxiety, and to induce the client to confront them directly (Barlow, 1988, 1993). On the other hand, some anxiety-inducing situations are not readily or judiciously reproducible in real life, as where they refer to memories of unique past events such as natural disasters, or where in vivo exposure to them might be objectively dangerous. For example, it is desirable for the traumatized rape victim to confront the circumstances surrounding the attack (Calhoun & Resick, 1993), but it would obviously be foolhardy to recommend that she patrol crime-infested neighborhoods at night. Imaginal procedures remain, therefore, a vital part of the therapeutic extinction armamentarium.

Reports on the effectiveness of implosive therapy and flooding have generally been very favorable (Emmelkamp, 1994); they may be considered the treatments of choice for simple phobias (Foa & Kozak, 1985) and perhaps an essential part of effective treatment for several other anxiety disorders, for instance, panic disorder with or without agoraphobia (Craske & Barlow, 1993), social phobia (Hope & Heimberg, 1993), and obsessive-compulsive disorder (Riggs & Foa, 1993). They have been used effectively in treating anxiety disorders in children (Kendall, 1994). Some investigators, however, have reported unfavorable as well as favorable results (Emmelkamp & Wessels, 1975; Mealiea, 1967; Wolpe, 1969b).

These mixed results appear to be particularly true of flooding in vivo. For example, Emmelkamp and Wessels (1975) found that flooding in vivo was terrifying for some clients. In one case, the agoraphobic client "hid in a cellar out of fear of being sent into the street for 90 minutes by the therapist" (p. 14). On the other hand, the flooding procedure can be made relatively bearable without diminished effectiveness for even a severely fearful client by increasing therapist support and active guidance during exposure, as was demonstrated by Williams and Zane (1989) in a study also involving the treatment of agoraphobia. In general, it appears that while many clients respond favorably to implosion or flooding, some do not respond, and a few suffer an exacerbation of their phobias. This finding suggests a need for caution in the use of these techniques, particularly because they involve experiences that may be traumatic.

A modified form of flooding that involves repeated exposure to the somatic cues usually preceding panic (for example, heart palpitations experienced at the beginning of a "false alarm"), rather than to traumatizing situations themselves, may provide a key to circumventing undesirable reactions to exposure treatment. Accumulating evidence shows that it is these sorts of cues that trigger full-blown anxiety attacks, and Barlow and associates (e.g., Barlow et al., 1989; Craske & Barlow, 1993) have developed effective procedures for extinguishing this type of chain reaction, for example, by teaching clients to self-induce their false alarm symptoms repeatedly ("interoceptive exposure"). In an important study in which the exposure to anticipatory cues procedure was a centerpiece in a treatment package for panic disorder, this treatment was demonstrated to be far superior to drug treatment with alprazolam (Xanax), a benzodiazepine compound touted as having strong antipanic properties, but one also noted for its addictive potential (Klosko et al., 1990).

## Systematic Desensitization

The process of extinction can be applied to behavior that is positively reinforced or negatively reinforced. Of the two, behavior that is negatively reinforced—reinforced by the successful avoidance of a painful situation—is harder to deal with. Because someone with negatively reinforced maladaptive behavior becomes anxious and withdraws at the first sign of the painful situation, he or she never gets a chance to find out whether the expected aversive consequences do in fact come about. In addition, the avoidance is anxiety-reducing and hence is itself reinforced.

One technique that has proven especially useful in extinguishing negatively reinforced behavior involves eliciting an antagonistic or competing response. Because it is difficult if not impossible to feel both pleasant and anxious at the same time, the method of **systematic desensitization** is aimed at teaching a person to relax or behave in some other way that is inconsistent with anxiety while in the presence (real or imagined) of the anxiety-producing stimulus. It may therefore be considered a type of counter-conditioning procedure. The term *systematic* refers to the carefully graduated manner in which the person is exposed to the feared stimulus, the procedural opposite of implosion and flooding. Systematic desensitization is not used exclusively to deal with avoidance behaviors brought about by negative reinforcement—that is, by successfully avoiding aversive experience. It can be used for other kinds of behavioral problems as well. In general, however, it is a Type A therapeutic procedure aimed at anxiety reduction.

The prototype of this approach is the classic experiment of Jones (1924), in which she successfully eliminated a small boy's conditioned fears of a white rabbit and other furry animals. First she brought the rabbit just inside the door at the far end of the room while the boy, Peter, was eating. On successive days, the rabbit was gradually brought closer until Peter could pat it with one hand while eating with the other.

Wolpe (1958; Rachman & Hodgson, 1980) elaborated on the procedure developed by Jones and devised the term *systematic desensitization* to refer to it. On the assumption that most anxiety-based patterns are, fundamentally, conditioned responses, Wolpe worked out a way to train a client to remain calm and relaxed in situations that formerly produced anxiety. Wolpe's approach is elegant in its simplicity, and his method is equally straightforward.

A client is taught to enter a state of relaxation, typically by progressive concentration on relaxing various muscle groups. Meanwhile, in collaboration with the therapist, an "anxiety hierarchy" is constructed consisting of imagined scenes graded as to their capacity to elicit anxiety. For example, were the problem one of disabling sexual anxiety, a low-anxiety scene might be a candlelight dinner with the prospective partner, while a high-anxiety scene might be imagining the penis actually entering the vagina.

Active therapy sessions consist of repeatedly imagining the scenes in the hierarchy under conditions of deep relaxation, beginning with the minimum anxiety items and gradually working toward those rated in the more extreme ranges. A session is terminated at any point where the client reports experiencing significant anxiety, the next session resuming at a lower point in the hierarchy. Treatment continues until all items in the hierarchy can be imagined without notable discomfort, by which point the client's real-life difficulties will typically have shown substantial improvement. The usual duration of a desensitization session is about 30 minutes, and the sessions are often given two to three times per week. The overall therapy program may, of course, take a number of weeks or even months. Kennedy and Kimura (1974) have shown, however, that even clients who have progressed only 25–50 percent of the way through their anxiety hierarchy show significant therapeutic gains.

Several variants of systematic desensitization have been devised. One variation involves the use of a tape recorder to enable a client to carry out the desensitization process at home. Another utilizes group desensitization procedures—as in "marathon" desensitization groups, in which the entire program is compressed into a few days of intensive treatment. One of the present authors routinely employs hypnosis to induce relaxation (the standard relaxation training can be quite tedious) and to achieve vividness in the imagining of hierarchy scenes. Perhaps the most important variation is in vivo desensitization, which is essentially similar to flooding but typically involves graduated exposure to the feared situations after a state of relaxation has been attained.

*Joseph Wolpe is shown here conducting systematic desensitization therapy to reduce a client's anxiety. The client, in a relaxed state, is told to imagine the weakest anxiety on her list of anxiety-producing stimuli. If she feels anxious, she is instructed to stop imagining and relax again.*

You will probably have concluded by this point that the truly essential element in the behavioral treatment of anxiety is repeated *exposure* of a client to the stimuli, even if only imaginally, that elicit the fear response, regardless of the methods employed in achieving that end. Despite some continued wrangling among proponents of one or another specific procedure, that conclusion appears to be fair and accurate. Where a therapist has a choice—that is, depending on the nature of the problem and on client cooperation and tolerance—in vivo procedures seem to have an edge in efficiency and possibly in ultimate efficacy over those employing imagery as the mode of confrontation (Emmelkamp, 1994). Overall, the outcome record for exposure treatments is impressive (Clum et al., 1993; Emmelkamp, 1994).

## Aversion Therapy

**Aversion therapy** involves modifying undesirable behavior by the old-fashioned method of punishment. Punishment may involve either the removal of desired reinforcers or the use of aversive stimuli, but the basic idea is to reduce the "temptation value" of stimuli that elicit undesirable behavior. The most commonly used aversive stimulus is electric shock, although drugs may also be used. As we will see, however, punishment is rarely employed as the sole method of treatment.

Apparently the first formal use of aversion therapy was made by Kantorovich (1930), who administered electric shocks to alcoholics in association with the sight, smell, and taste of alcohol, an early version of the Antabuse drug treatment in use today (Antabuse produces nausea when a person drinks alcohol—see Chapter 10). Since that time, aversion therapy has been used in the treatment of a wide range of maladaptive behaviors, including smoking, drinking, overeating, drug dependence, gambling, sexual deviance, and bizarre psychotic behavior. As normally employed, it is a Type R therapeutic procedure, targeted at suppression of problematic responses. Because we have described the use of aversion therapy earlier in the course of our discussion of certain abnormal behavior patterns, we will restrict ourselves here to a review of a few brief examples and principles.

Lovaas (1977) found punishment by electric shock to be effective in extreme cases of severely disturbed autistic children. In one case, a seven-year-old autistic boy, diagnosed as severely retarded, had to be kept in restraints 24 hours a day because he would continually beat his head with his fists or bang it against the walls of his crib, inflicting serious injuries. Though it may seem paradoxical to employ punishment to reduce the frequency of self-destructive behavior, electric shock following this behavior was nevertheless effective, bringing about complete inhibition of the maladaptive behavior pattern in a relatively short time (Bucher & Lovaas, 1967).

The use of electric shock as an aversive stimulus, however, has generally diminished in recent years because of the ethical and "image" problems involved in its use and because the new behaviors induced by it do not automatically generalize to other settings (Harris & Ersner-Hershfield, 1978). Also, less dangerous and more effective procedures have been found. The method of choice today is probably differential reinforcement of other responses (DOR), in which behaviors incompatible with the undesired behavior are positively reinforced. For example, for a child who indulges in antisocial, destructive behavior, positive reinforcement might be used for every sign of constructive play. At the same time, any reinforcement that has been maintaining maladaptive behavior is removed. Lovaas and colleagues, who first reported the successful use of electric shock with autistic children, now recommend the use of nonpunitive treatment for self-injurious behavior (Russo, Carr, & Lovaas, 1980).

Aversion therapy is primarily a way—often quite an effective one—of stopping maladaptive responses for a brief period of time. With this interruption, an opportunity exists for substituting new behavior or for changing a lifestyle by encouraging more adaptive alternative patterns that will prove reinforcing in themselves. This point is particularly important because otherwise a client may simply refrain from maladaptive responses in "unsafe" therapy situations, where such behavior leads to immediate aversive results, but keep making them in "safe" real-life situations, where there is no fear of immediate discomfort. Also, there is little likelihood that a previously gratifying but maladaptive behavior pattern will be permanently relinquished unless alternative forms of gratification are learned during the aversion therapy. A therapist who believes it possible to "take away" something without "giving something back" is likely to be disappointed. This is an important point in regard to the treatment of addictions and paraphilias, one often not appreciated in otherwise well-designed treatment programs.

## Modeling

As Bandura (1977b) has pointed out,

> Learning would be exceedingly laborious, not to mention hazardous, if people had to rely solely on the effects of their own actions to inform them what to do. Fortunately, most human behavior is learned observationally through modeling: from observing others one forms an idea of how new behaviors are performed, and on later occasions this coded information serves as a guide for action. Because people can learn from example what to do, at least in approximate form, before performing any behavior, they are spared needless error. (p. 22)

Although reinforcement of modeled behavior can influence whether an observer-learner attends to a model's actions and strengthens the response imitated, observational learning does not seem to require extrinsic reinforcement. Rather, according to Bandura, reinforcement functions as a facilitative condition to learning. Anticipation of a reinforcement may also make a person more likely to perform a behavior.

As the name implies, **modeling** involves the learning of skills through imitating another person, such as a parent or therapist, who performs the behavior; as such, it is a Type R procedure. A client may be exposed to behaviors or roles in peers or therapists and encouraged to imitate the desired new responses. For example, modeling may be used to promote the learning of simple skills, such as self-feeding in a profoundly mentally retarded child, or more complex ones, such as being more effective in social situations for a shy, withdrawn adolescent.

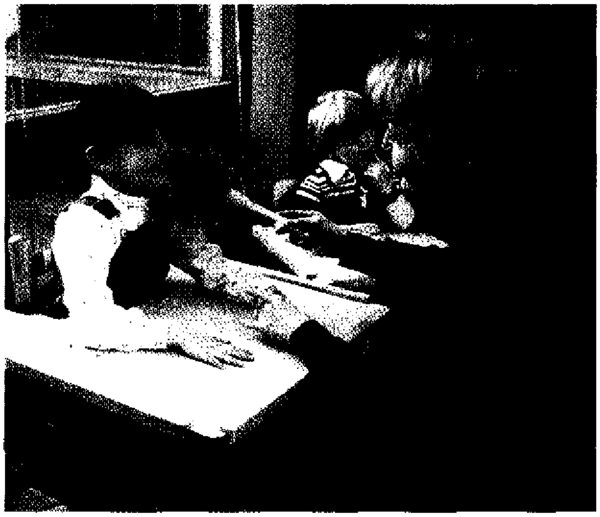
As we have noted, modeling and imitation are used in various forms of behavior therapy. Bandura (1964) found that live modeling of fearlessness combined with instruction and guided participation is the most effective desensitization treatment, resulting in the elimination of snake phobias in over 90 percent of the cases treated.

## Systematic Use of Reinforcement

Often referred to as ***contingency management***, systematic programs involving the use of reinforcement to elicit and maintain effective behavior (Type R therapy) have achieved notable success, particularly in institutional settings. Response shaping, token economies, and behavioral contracting are among the most widely used of such techniques.

**Response Shaping** Positive reinforcement is often used in **response shaping,** that is, in establishing by gradual approximation a response that is not initially in an individual's behavior repertoire. This technique has been used extensively in working with children's behavior problems. The following case reported by Wolf, Risley, and Mees (1964) is illustrative:

> A 3-year-old autistic boy lacked nominal verbal and social behavior. He did not eat properly, engaged in self-destructive behavior, such as banging his head and scratching his face, and manifested ungovernable tantrums. He had recently had a cataract operation, and required glasses for the development of normal vision. He refused to wear his glasses, however, and broke pair after pair.
>
> The technique of shaping was decided on to counteract the problem with his glasses. Initially, the boy was trained to expect a bit of candy or fruit at the sound of a toy noisemaker. Then training was begun with empty eyeglass frames. First the boy was reinforced with the candy or fruit for picking them up, then for holding them, then for carrying them around, then for bringing the frames closer to the eyes, and then for putting the empty frames on his head at any angle. Through successive approximations, the boy finally learned to wear his glasses up to twelve hours a day.



*Positive reinforcement is an effective technique for managing behavior problems, with food or other treats or privileges often used as reinforcers. This autistic child is being reinforced for some positive behavior by being stroked with a feather tickler.*

**Token Economies** Approval and other intangible reinforcers may be ineffective in behavior modification programs, especially those dealing with severely maladaptive behavior. In such instances, appropriate behaviors may be rewarded with tangible reinforcers in the form of tokens that can later be exchanged for desired objects or privileges (Kazdin, 1980). In working with hospitalized schizophrenic clients, for example, Ayllon and Azrin (1968) found that using the commissary, listening to records, and going to movies were considered highly desirable activities by most clients. Consequently, these activities were chosen as reinforcers for socially appropriate behavior. To participate in any of them, a client had to earn a number of tokens by demonstrating appropriate ward behavior. In Chapter 18, we will describe another token economy program, an extraordinarily successful one, with chronic hospitalized clients who had been considered resistant to treatment (Paul, 1982; Paul & Lentz, 1977).

**Token economies** have been used to establish adaptive behaviors ranging from elementary responses, such as eating and making one's bed, to the daily performance of responsible hospital jobs. In the latter instance, the token economy resembles the outside world where an individual is paid for his or her work in tokens (money) that can later be exchanged for desired objects and activities. The use of tokens as reinforcers for appropriate behavior has a number of distinct advantages: (a) the number of tokens earned depends directly on the amount of desirable behavior shown; (b) tokens, like money in the outside world, may be made a general medium of currency in terms of what they will "purchase"; hence they are not readily subject to satiation and tend to maintain their incentive value; (c) tokens can reduce the delay that often occurs between appropriate performance and reinforcement; (d) the number of tokens earned and the way in which they are "spent" are largely up to the client; and (e) tokens tend to bridge the gap between the institutional environment and the demands and system of payment that will be encountered in the outside world.

The ultimate goal in token economies, as in other programs of extrinsic reinforcement, is not only to achieve desired responses but to bring such responses to a level where their adaptive consequences will be reinforcing in their own right—thus enabling natural rather than artificial rewards to maintain the desired behavior. For example, extrinsic reinforcers may be used initially to help children overcome reading difficulties, but once a child becomes proficient in reading, this skill will presumably provide intrinsic reinforcement as the child comes to enjoy reading for its own sake.

Although their effectiveness has been clearly demonstrated with chronic schizophrenic clients, mentally retarded residents in institutional settings, and children, the use of token economies has not been extensive in recent years (Paul & Menditto, 1992). In part, this neglect is a result of budget-inspired reductions in trained hospital treatment staffs, which are required for the effective management of such programs. Token economies are also poorly understood by lay persons, many of whom see them as inhumane or crassly manipulative. If these people are "sick," so the thought goes, they should have medicine and not be expected to "perform" for simple amenities. Unfortunately, such thinking makes for chronic social disability.

**Behavioral Contracting** A technique called **behavioral contracting** is used in some types of psychotherapy and behavior therapy to identify the behaviors that are to be changed and to maximize the probability that these changes will occur and be maintained (Nelson & Mowry, 1976). By definition, a contract is an agreement between two or more parties—such as a therapist and a client, a parent and a teenager, or a husband and a wife—that governs the nature of an exchange. The agreement, often in writing, specifies a client's obligations to change as well as the responsibilities of the other party to provide something the client wants in return, such as tangible rewards, privileges, or therapeutic attention. Behavior therapists frequently make behavioral contracting an explicit focus of treatment, thus helping establish the treatment as a joint enterprise for which both parties have responsibility.

Behavioral contracting can facilitate therapy in several ways: (a) the structuring of the treatment relationship can be explicitly stated, giving the client a clear idea of each person's role in the treatment; (b) the actual responsibilities of the client are outlined and a system of rewards is built in for changed behavior; (c) the limitations of the treatment, in terms of the length and focus of the sessions, are specified; (d) by agreement, some behaviors (for example, the client's sexual orientation) may be eliminated from the treatment focus, thereby establishing the "appropriate content" of the treatment sessions; (e) clear treatment goals can be defined; and (f) criteria for determining success or failure in achieving these goals can be built into the program.

Sometimes a contract is negotiated between a disruptive child and a teacher, according to which the child will maintain or receive certain privileges as long as he or she behaves in accordance with the contract. Usually the school principal is also a party to such a contract to ensure the enforcement of certain conditions that the teacher may not be in a position to enforce, such as removing the child from the classroom for engaging in certain types of misbehavior. Another common application of contracting is in behavioral couples therapy, where the principles governing the exchange of "reinforcements" between the distressed parties is formally negotiated and sometimes even committed to writing (e.g., Cordova & Jacobson, 1993). These techniques have a good record in outcome studies (Shadish et al., 1993).

We know of no therapist who seriously believes in the long-term feasibility of such formal therapeutic contracts as a means of regulating interpersonal behavior. Rather, as in the case of aversion therapy, contracts provide an opportunity to interrupt for a time self-sustaining dysfunctional behavior, thus permitting the emergence of new responses that may prove more adaptive and satisfying.

## Assertiveness Therapy

**Assertiveness therapy** or training has been used as an alternative to relaxation in the desensitization procedure and as a means of developing more effective coping techniques. It appears particularly useful in helping people who have difficulties in interpersonal interactions because of anxiety responses that may prevent them from speaking up, claiming their rights, or even from showing appropriate affection. Such inhibition may lead to continual inner turmoil, particularly if a person feels strongly about a situation. Assertiveness therapy may also be indicated in cases where individuals consistently allow others to take advantage of them or maneuver them into uncomfortable situations.

Assertiveness is viewed as the open and appropriate expression of thoughts and feelings, with due regard to the rights of others (Lange & Jakubowski, 1976). Assertiveness training programs typically follow stages in which the desired assertive behaviors are first practiced in a therapy setting. Then, guided by the therapist, the client is encouraged to practice the new, more appropriately assertive behaviors in real-life situations. Often attention is focused on developing more effective interpersonal skills. For example, a client may learn to ask the other person such questions as "Is anything wrong? You don't seem to be your usual self today." Such questions put the focus on the other person without suggesting an aggressive or hostile intent on the part of the speaker. Each act of intentional assertion is believed to inhibit the anxiety associated with the situation and therefore to weaken the maladaptive anxiety-response pattern. At the same time, it tends to foster more adaptive interpersonal behaviors. Assertiveness therapy is a Type R procedure.

Although assertiveness therapy is a highly useful procedure in certain types of situations, it does have limitations. For example, Wolpe (1969b) has pointed out that it is largely irrelevant for phobias involving nonpersonal stimuli. It may also be of little use in some types of interpersonal situations; for instance, if a person has been rejected by someone, assertive behavior may tend to aggravate rather than resolve the problem. However, in interpersonal situations where maladaptive anxiety can be traced to lack of self-assertiveness, this type of therapy appears particularly effective.

## Biofeedback Treatment

Historically it was generally believed that voluntary control over physiological processes, such as heart rate, galvanic skin response, and blood pressure, was not possible. In the early 1960s, however, this view began to change. A number of investigators, aided by the development of sensitive electronic instruments that could accurately measure physiological responses, demonstrated that many of the processes formerly thought to be "involuntary" were modifiable by learning procedures—operant learning and classical conditioning. Kimmel (1974) demonstrated, for example, that the galvanic skin response could be conditioned by operant learning techniques.

The importance of the autonomic nervous system in the development of abnormal behavior has long been recognized. For example, autonomic arousal is an important factor in anxiety states. Thus many researchers have applied techniques developed in the autonomic conditioning studies in an attempt to modify the internal environment of troubled persons to bring about more adaptive behavior—for instance, to modify heart rates in clients with irregular heartbeats (Weiss & Engel, 1971), to treat stuttering by feeding back information on the electric potential of muscles in the speech apparatus (Lanyon, Barrington, & Newman, 1976), and to reduce lower-back pain (Wolf, Nacht, & Kelly, 1982) and chronic headaches (Blanchard et al., 1983).

This Type P treatment approach—in which a person is taught to influence his or her own physiological processes—is referred to as **biofeedback.** Several steps are typical in the process of biofeedback treatment: (a) monitoring the physiological response that is to be modified (perhaps blood pressure or skin temperature); (b) converting the information to a visual or auditory signal; and (c) providing a means of prompt feedback—indicating to a subject as rapidly as possible when the desired change is taking place (Blanchard & Epstein, 1978). Given this feedback, the subject may then seek to reduce his or her emotionality, as by lowering the skin temperature. For the most part, biofeedback is oriented to reducing the reactivity of some organ system innervated by the autonomic nervous system—very often a physiological component of the anxiety response.

Although there is general agreement that many physiological processes can be regulated to some extent by learning, the application of biofeedback procedures to alter abnormal behavior has produced equivocal results. Demonstrations of clinical biofeedback applications abound, but carefully controlled research has often not supported earlier impressions of widespread clinically significant improvement.

Blanchard and Young (1973, 1974) pointed out that the effects of biofeedback procedures are generally small and often do not generalize to situations outside the laboratory, where the biofeedback devices are not present. Two well-controlled studies failed to show a significant treatment effect for biofeedback in persons with migraine (Kewman & Roberts, 1979) or Raynaud's disease (Gugliemi, 1979). On the other hand, tension headache victims may respond more favorably to biofeedback (Blanchard, 1994). Also, Flor and Birbaumer (1993) demonstrated in a well-controlled recent study a rather impressive effect of electromyographic (muscle tension) biofeedback in the control of musculoskeletal pain of the back and jaw, one that survived a 24-month follow-up.

Unfortunately, this study did not include a relaxation training comparison group. Where that comparison has been made, biofeedback usually has not been shown to be any more effective than relaxation training, leading to the suggestion that biofeedback may simply be a more elaborate (and usually more costly) means of teaching clients relaxation (Blanchard & Epstein, 1978; Blanchard et al., 1980; Tarler-Beniolo, 1978). Relaxation training, in itself, continues to amass a very creditable record in the treatment of various medical conditions, as shown in a recent quantitative review by Carlson and Hoyle (1993). Although no final judgment on this matter can as yet be made, we would note that—as with almost any treatment procedure—a small percentage of clients may be expected to show an unusually good response to biofeedback treatment.

### Evaluation of Behavior Therapy

Compared with psychoanalytic and other psychotherapies, behavior therapy appears to have three distinct advantages. First, the treatment approach is precise. The target behaviors to be modified are specified, the methods to be used are clearly delineated, and the results can be readily evaluated (Marks, 1982). Second, the use of explicit learning principles is a sound basis for effective interventions as a result of their demonstrated scientific validity (Kazdin & Wilson, 1978). Third, the economy of time and costs is quite good. Not surprisingly, then, the overall outcomes achieved with behavior therapy compare very favorably with those of other approaches (Smith et al., 1980). Behavior therapy usually achieves results in a short period of time because it is generally directed to specific symptoms, leading to faster relief of a client's distress and to lower costs.

As with other approaches, the range of effectiveness of behavior therapy is not unlimited, and it works better with certain kinds of problems than with others. Generally, the more pervasive and vaguely defined the client's problem, the less likely that behavior therapy will be useful. For example, it appears to be only rarely employed to treat Axis II personality disorders, where specific symptoms are rare. On the other hand, behavioral techniques are the backbone of modern approaches to treating sexual dysfunctions, as discussed in Chapter 11. Quantitative reviews of therapeutic outcomes confirms the expectation that behavior therapy has a particular place in the treatment of anxiety disorders, where the powerful Type A exposure techniques of behavior therapy can be brought to bear (Andrews & Harvey, 1981; Clum et al., 1993; Smith et al., 1980). Smith and colleagues' (1980) quantitative review in fact reveals the less expected finding of a relatively good outcome record with the psychoses. Thus, although behavior therapy is not a cure-all, it has earned in a relatively brief period a highly respected place among the available psychosocial treatment approaches.

## COGNITIVE-BEHAVIOR THERAPY

As we have seen, early behavior therapists focused on observable behavior. They regarded the inner thoughts of their clients as not really part of the causal chain, and in their zeal to be objective they focused on the relationship between observable behaviors and observable reinforcing conditions. Thus they were often viewed as mechanistic technicians who simply manipulated their clients without considering them as people. Other behavior therapists such as Wolpe did not attend exclusively to overt behavior given that he did use systematic exposure to imagined frightening scenes as a therapeutic technique. Nevertheless, his focus was not on the role of cognitive processes per se in psychopathology, and clearly his therapeutic techniques did not try to manipulate cognitive processes directly.

Starting in the 1970s, however, a number of behavior therapists began to reappraise the importance of "private events"—thoughts, perceptions, evaluations, and self-statements—seeing them as processes that mediate the effects of objective stimulus conditions and thus help determine behavior and emotions (Borkovec, 1985; Mahoney & Arnkoff, 1978). If they help to determine behavior and emotions, including maladaptive behavior and emotions, then perhaps they can be changed so as to correct maladaptive behaviors and emotions.

Homme (1965), a student of Skinner, began this exodus from strict behaviorism in a paper arguing that these private events were behaviors that could be objectively analyzed. He proposed, as had Dollard and Miller (1950) earlier, that thoughts be regarded as emitted internal events comparable to emitted external behaviors, and that a technology be developed for modifying thoughts by using the same learning principles that were proving so effective in changing outer behavior. These internal, private events he called *coverants,* considering them to be operants of the mind. Following Homme's "coverant behaviorism," many investigators began to study the role of covert events, such as thoughts and assumptions, in psychopathology and began to develop methods to manipulate them.

As the term suggests, **cognitive-behavior therapy** stems from both cognitive psychology, with its emphasis on the effects of thoughts on behavior and on the study of the very nature of our cognitive processes, and behaviorism, with its rigorous methodology and performance-oriented focus. At the present time, there is no single set of techniques that define cognitive-behavior therapy: Numerous methods are being developed with varying emphases. Two main themes seem to characterize them all, however: (a) the conviction that cognitive processes influence affect, motivation, and behavior; and (b) the use of cognitive and behavior-change techniques in a pragmatic (hypothesis-testing) manner. That is, much of the content of the therapy sessions and homework assignments is analogous to experiments in which a therapist and a client apply learning principles to alter the client's cognitions, continuously evaluating the effects that the changes in cognitions have on subsequent thoughts, feelings, and overt behavior.

The exact nature of the relationship between emotion, cognition, and behavior, a venerable problem whose philosophical roots are in the distant past, is far from clear even today. Can it be, for example, that thoughts, by some accounts ephemeral and immaterial in nature, cause emotions and behavior? Any serious discussion of such an issue would take us far afield, but it is important to understand that the intellectual status of cognitive therapy fuels some controversy. Aaron Beck (Beck & Weishaar, 1989), an important leader in the field, acknowledges that disordered cognitions are not a cause of abnormal behavior or emotions, but rather are an intrinsic (yet alterable) element of such behavior and emotions. If the critical cognitive components can be changed, according to this view, then the behavior and maladaptive emotions will change. Because altering cognitions is central in these therapies, we consider them to be Type C approaches. In our discussion, we will focus on three approaches to cognitive-behavior therapy: the rational-emotive therapy of Albert Ellis, the stress-inoculation training of Donald Meichenbaum, and the cognitive-behavior therapies of Beck.

## Rational-Emotive Therapy

One of the earliest behaviorally oriented cognitive therapies (developed considerably before Homme's influential paper) was the **rational-emotive therapy (RET)** of Albert Ellis (1958, 1973, 1975, 1989). RET attempts to change a client's basic maladaptive thought processes, on which maladaptive emotional responses and thus behavior are presumed to depend. In its infancy, RET was viewed skeptically by many professionals who doubted its effectiveness, but it has now become one of the most widely used therapeutic approaches (Ellis, 1989).

Ellis posited that a well-functioning individual behaves rationally and in tune with empirical reality. For Ellis, thoughts do have causal primacy in behavior, notably emotional behavior. Unfortunately, many of us have learned unrealistic beliefs and perfectionistic values that cause us to expect too much of ourselves, leading us to behave irrationally and then to feel unnecessarily that we are worthless failures. For example, a person may continually think, "I should be able to win everyone's love and approval" or "I should be thoroughly adequate and competent in everything I do." Such unrealistic assumptions and self-demands inevitably lead to ineffective and self-defeating behavior in the real world, which reacts accordingly, and then to the recognition of failure and the emotional response of self-devaluation. This emotional response is thus the necessary consequence not of "reality," but of an individual's faulty expectations, interpretations, and self-demands.

As a more specific example, consider a man who has an intense emotional reaction of despair with deep feelings of worthlessness, unlovability, and self-devaluation when he is jilted by his fiancée. With a stronger self-concept and a more realistic picture of both himself and his fiancée, as well as of their actual relationship, his emotional reaction might have been one of relief. It is his interpretation of the situation and of himself, rather than the objective situation, that has led to his intense emotional reaction.

Ellis (1970) believed that one or more of the following core irrational beliefs are at the root of most psychological maladjustment:

- One should be loved by everyone for everything one does.
- Certain acts are awful or wicked, and people who perform them should be severely punished.
- It is horrible when things are not the way we would like them to be.
- If something may be dangerous or fearsome, one should be terribly upset about it.
- It is better to avoid life problems if possible than to face them.

- One needs something stronger or more powerful than oneself to rely on.
- One should be thoroughly competent, intelligent, and achieving in all respects.
- Because something once affected one's life, it will indefinitely affect it.
- One must have certain and perfect self-control.
- Happiness can be achieved by inertia and inaction.
- We have virtually no control over our emotions and cannot help having certain feelings.

Irrationality can, however, be viewed in different ways. Arnkoff and Glass (1982) cautioned against an overly simplistic view of irrational behavior as the mere holding of irrational beliefs. Rather, they contended that irrationality may also involve faulty thought processes reflecting a "close-mindedness" that is more resistant to change than Ellis's view suggests. Moreover, it is also a mistake to think that people without any kind of psychopathology always think and behave in a rational manner. Instead, most of us have a variety of positive illusions that contribute to our not being anxious or depressed (e.g., Bandura, 1986; Taylor & Brown, 1988).

The task of rational-emotive therapy is to restructure an individual's belief system and self-evaluation, especially with respect to the irrational "shoulds," "oughts," and "musts" that are preventing a more positive sense of self-worth and a creative, emotionally satisfying, and fulfilling life. Several methods are used. One method is to dispute a person's false beliefs through rational confrontation. For example, an RET therapist dealing with the jilted young man previously discussed might ask, "Why should your fiancée's changing her mind mean that you are worthless?" Here the therapist would teach the client to identify and dispute the beliefs that were producing the negative emotional consequences.

A rational-emotive therapist also uses behaviorally oriented techniques, usually to help clients practice living in accord with their new beliefs and philosophy. Sometimes, for example, homework assignments are given to encourage clients to have new experiences and break negative chains of behavior. For example, clients might be instructed to reward themselves by an external reinforcer, such as a food treat, after working 15 minutes at disputing their beliefs. Another method of self-reinforcement might be through covert self-statements such as "You are doing a really good job."

Although the techniques vary dramatically, in some ways the philosophy underlying rational-emotive therapy can be viewed as somewhat similar to that underlying humanistic therapy (to be discussed in a later section) because both take a clear stand on personal worth and human values. Rational-emotive therapy aims at increasing an individual's feelings of self-worth and clearing the way for self-actualization by removing the false beliefs that have been stumbling blocks to personal growth.

## Stress-Inoculation Therapy

A second cognitive-behavioral approach to treatment is **stress-inoculation therapy**—a type of self-instructional training focused on altering self-statements an individual routinely makes in stress-producing situations. Here the approach is to restructure these statements so as to improve functioning under stressful conditions (Meichenbaum & Cameron, 1982). Like other cognitive-behavior therapies, stress-inoculation therapy assumes that a person's problems result from maladaptive beliefs that are leading to negative emotional states and maladaptive behavior, familiar elements in the causal chain cognitive theorists have posited.

Stress-inoculation therapy usually involves three stages. In the initial phase, cognitive preparation, client and therapist together explore the client's beliefs and attitudes about the problem situation and the self-statements to which they are leading. The focus is on how the person's self-talk can influence later performance and behavior. Together, the therapist and the client agree on new self-statements that would be more adaptive. Then the second phase of the stress inoculation, skill acquisition and rehearsal, is begun. In this phase, more adaptive self-statements are learned and practiced. For example, a person undergoing stress-inoculation therapy for coping with the "feeling of being overwhelmed" would rehearse self-statements such as,

- When fear comes, just pause.
- Keep the focus on the present; what is it you have to do?
- Label your fear from 0 to 10 and watch it change.
- You should expect your fear to rise.
- Don't try to eliminate fear totally; just keep it manageable.
- You can convince yourself to do it. You can reason fear away.
- It will be over shortly.
- It's not the worst thing that can happen.

- Just think about something else.
- Do something that will prevent you from thinking about fear.
- Describe what is around you. That way you won't think about worrying. (Meichenbaum, 1974, p. 16)

The third phase of stress-inoculation therapy, application and practice, involves applying the new coping strategies in actual situations. This practice is graduated in such a way that the client attempts easier situations first and only gradually enters more stressful situations as he or she feels confident of mastering them.

## Beck's Cognitive-Behavior Therapies

Beck's cognitive-behavior approach was originally developed for the treatment of depression (Beck et al., 1979; Hollon & Beck, 1978) and was later extended to anxiety disorders, eating disorders and obesity, conduct disorder in children, personality disorders, and substance abuse (Beck, 1985; Beck & Emery, 1985; Beck et al., 1990, 1993; Hollon & Beck, 1994). One basic assumption underlying this approach is that problems like depression result from clients' illogical thinking about themselves, the world they live in, and the future.

In the initial phases clients are taught the connection between their patterns of thinking and their emotional responses. They are taught to identify their own automatic thoughts and to keep records of their thought content and their emotional reactions. By then learning, with the therapist's help, about the logical errors in their thinking, they learn to challenge the validity of these automatic thoughts. The logical errors in their thinking lead them to (a) selectively perceive the world as harmful while ignoring evidence to the contrary; (b) overgeneralize on the basis of limited examples—for example, seeing themselves as totally worthless because they were laid off at work; (c) magnify the significance of undesirable events—for example, seeing the job loss as the end of the world for them; and (d) engage in absolutistic thinking—for example, exaggerating the importance of someone's mildly critical comment and perceiving it as proof of their instant descent from goodness to worthlessness.

In Beck's cognitive-behavior therapy, clients are not persuaded to change their beliefs by debate and persuasion as in rational-emotive therapy; rather, they are encouraged to gather information about themselves through unbiased experiments that allow them to disconfirm their false beliefs. Together, a therapist and a client identify the client's beliefs and expectations and formulate them as hypotheses to be tested. They then design ways in which the client can check out these hypotheses in the real world. These disconfirmation experiments are planned to give the individual successful experiences, thereby interrupting the destructive sequence previously described. They are arranged according to difficulty, so that the least difficult (or risky) tasks will be accomplished successfully before the more difficult ones are attempted (see HIGHLIGHT 17.4).

In the treatment of depression, sometimes a client and a therapist schedule the client's daily activities on an hour-by-hour basis. Such activity scheduling is an important part of therapy with depressed individuals because by reducing such clients' inactivity, it interrupts their tendencies to ruminate about themselves. An important part of the arrangement is the scheduling of pleasurable events, because many depressed clients have lost the capacity for gaining pleasure from their own activities. Both the scheduled pleasurable activities and the rewarding experiences that derive from carrying out the behavioral experiments tend to increase an individual's satisfaction and positive mood.

Besides planning the behavioral assignments, evaluating the results in subsequent sessions, and planning further disconfirmation experiments, such therapy sessions for depression include several other cognitive emphases. For example, the client is encouraged to discover underlying dysfunctional assumptions or depressogenic schemas that may be leading to self-defeating tendencies. These generally become evident over the course of therapy as the client and the therapist examine the themes of the client's automatic thoughts. Because these depressogenic schemas are seen as creating the person's vulnerability to depression, this phase of treatment is considered essential in ensuring resistance to relapse when the client faces stressful life events in the future. That is, without changing the underlying cognitive vulnerability factors, the client may show short-term improvement but will still be subject to recurrent depression.

The general approach is similar for disorders other than depression, although the exact focus of the treatment, of course, differs if one is treating a client with panic disorder, generalized anxiety, bulimia, or substance abuse. For example, as was seen in Chapter 5, in panic disorder the focus is on identifying the automatic thoughts about feared bodily sensations and on teaching the client to correct logical errors in those automatic thoughts—basically to decatastrophize the experience of panic (Clark, 1988). For

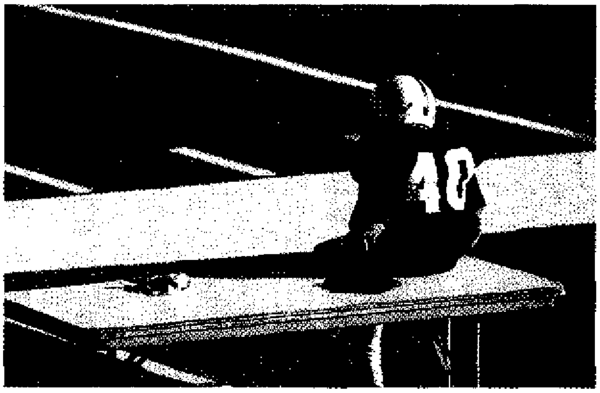
17.4

## Cognitive-Behavioral Therapy for a Case of Depression

Rush, Khatami, and Beck (1975) have reported several cases of successful treatment using cognitive clarification and behavioral assignments for clients with recurring chronic depression. The following case illustrates their approach:

> A 53-year-old white male engineer's initial depressive episode 15 years ago necessitated several months' absence from work. Following medication and psychotherapy, he was asymptomatic up to four years ago. At that time, sadness, pessimism, loss of appetite and weight, and heavy use of alcohol returned.
>
> Two years later, he was hospitalized for six weeks and treated with lithium and imipramine. He had three subsequent hospitalizations with adequate trials of several different tricyclics [antidepressant drugs]. During his last hospitalization, two weeks prior to initiating cognitive-behavioral therapy, he was treated with 10 sessions of ECT [electroconvulsive therapy]. His symptoms were only partially relieved with these various treatments.
>
> When the client started cognitive-behavioral therapy, he showed moderate psychomotor retardation. He was anxious, sad, tearful, and pessimistic. He was self-depreciating and self-reproachful without any interest in life. He reported decreased appetite, early morning awakening, lack of sexual interest, and worries about his physical health. Initially he was treated with weekly sessions for 3 months, then biweekly for 2 months. Treatment, terminated after 5 months, consisted of 20 sessions. He was evaluated 12 months after the conclusion of therapy.
>
> Therapist and client set an initial goal of his becoming physically active (i.e., doing more things no matter how small or trivial). The client and his wife kept a separate list of his activities. The list included raking leaves, having dinner, and assisting his wife in apartment sales, etc. His cognitive distortions were identified by comparing his assessment of each activity with that of his wife. Alternative ways of interpreting his experiences were then considered.
>
> In comparing his wife's resume of his past experiences, he became aware that he had (1) undervalued his past by failing to mention many previous accomplishments, (2) regarded himself as far more responsible for his "failures" than she did, and (3) concluded that he was worthless since he had not succeeded in attaining certain goals in the past. When the two accounts were contrasted he could discern many of his cognitive distortions. In subsequent sessions, his wife continued to serve as an "objectifier." In midtherapy, the client compiled a list of new attitudes that he had acquired since initiating therapy.
>
> These included:
>
> (1) I am starting at a lower level of functioning at my job, but it will improve if I persist.
> (2) I know that once I get going in the morning, everything will run all right for the rest of the day.
> (3) I can't achieve everything at once.
> (4) I have my periods of ups and downs, but in the long run I feel better.
> (5) My expectations from my job and life should be scaled down to a realistic level.
> (6) Giving in to avoidance never helps and only leads to further avoidance.
>
> He was instructed to reread this list daily for several weeks even though he already knew the content. The log was continued, and subsequent assumptions reflected in the log were compared to the assumptions listed above.
>
> As the client became gradually less depressed, he returned to his job for the first time in 2 years. He undertook new activities (e.g., camping, going out of town) as he continued his log. (pp. 400–401)

The focus of the therapy was on encouraging the client to restructure his thought content—to reduce the negative self-judgments and to evaluate his actual achievements more realistically. Making and reviewing the list of new attitudes gave the client more perspective on his life situation, which resulted in an improved mood, less self-blame, and more willingness to risk alternative behavior.



*The negative emotional impact of situations and events such as rejection and isolation can lead to "catastrophizing," which may increase performance deficits. Cognitive therapy is "decatastrophizing."*

generalized anxiety disorder, the client is taught to correct the tendencies to overestimate the presence and likelihood of danger and to underestimate his or her ability to cope in a variety of situations (Beck & Emery, 1985). In bulimia, the cognitive approach proposes that the person has overvalued ideas about body weight and shape, which are often fueled by low self-esteem and fears of being unattractive. These beliefs are thought to lead to a tendency to diet excessively, which in turn increases the probability of losing control by bingeing and purging. The cognitive part of the treatment involves getting these clients to identify and change their maladaptive beliefs regarding weight and body image, as well as about what foods are "safe" or "dangerous" (Agras, 1993; Fairburn et al., 1993).

## Evaluation of Cognitive-Behavior Therapies

In spite of the widespread attention and popularity that Ellis's rational-emotive therapy has enjoyed, surprisingly little research has been conducted to document its efficacy—especially for carefully diagnosed clinical populations (Hollon & Beck, 1986). It has been shown to be useful in reducing test anxiety and speech anxiety, but it is inferior to exposure-based therapies in the treatment of more severe anxiety disorders such as agoraphobia and social phobia (Haaga & Davison, 1989, 1992). It hasn't yet been compared with cognitive or interpersonal therapy for the treatment of depression (discussed in Chapter 6), so we don't know whether it is as effective as these two proven treatments. In general, it may be most useful in helping generally healthy people to cope better with everyday stress and perhaps prevent them from developing full-blown anxiety or depressive disorders (Haaga & Davison, 1989, 1992).

Stress-inoculation therapy has been successfully used with a number of clinical problems, especially anger (Novaco, 1977, 1979), pain (Turk, Meichenbaum, & Genest, 1983; see Masters et al., 1986, for a review), Type A behavior (Jenni & Wollersheim, 1979), and mild forms of anxiety (Meichenbaum, 1975). (See also Denicola & Sandler, 1980; Holcomb, 1979; Klepac et al., 1981.) This approach is particularly suited to increasing the adaptive capabilities of individuals who have shown a vulnerability to developing problems in certain stressful situations. In addition to its value as a therapeutic technique for identified problems, stress-inoculation therapy may be a useful method for preventing behavior disorders. Although the preventive value of this and other cognitive-behavioral therapy procedures has not been demonstrated by empirical study, many believe that the incidence of maladjustment might be reduced if more individuals' general coping skills were improved (Meichenbaum & Jaremko, 1983).

A review of research evaluating Beck's type of cognitive-behavioral treatment methods suggests that these approaches to intervention are extremely effective in alleviating many different types of disorders (see Hollon & Beck, 1994, for a comprehensive review). In the case of depression, considerable evidence, reviewed in Chapter 6, suggests that cognitive-behavior therapy is at least comparable to drug treatment in all but perhaps the most severe cases (e.g., psychotic depression). Moreover, it has superior long-term advantages; several studies have shown that relapse in the one to two years of post-treatment was less likely if a client had been treated with cognitive therapy, whether or not there was also treatment with antidepressant drugs (Evans et al., 1992; Simons et al., 1986).

Although clinical depression was the first disorder for which there was good documented efficacy, many empirical studies in the past decade have compared cognitive-behavioral methods with other treatment approaches for a variety of other clinical disorders. The most dramatic recent results have been in the treatment of panic disorder and generalized anxiety disorder, but cognitive-behavior therapy is also now seen as the treatment of choice for bulimia and conduct disorder in children (Hollon & Beck, 1994). There are also promising results in the treatment of substance abuse (Beck et al., 1993) and of certain personality disorders (Beck et al., 1990; Linehan, 1993).

The combined use of cognitive and behavior therapy approaches is growing rapidly. There remains disagreement about whether the effects of cognitive-behavioral treatments are actually mediated by cognitive change, as the cognitive theorists propose (Hollon & Beck, 1994; Hollon, DeRubeis, & Evans, 1987). But at least for depression and panic disorder it does appear that cognitive change is the best predictor of long-term outcome, as would be predicted by cognitive theory (Clark et al., 1993; Hollon, Evans, & DeRubeis, 1990). We anticipate that in the next few years more attention will be devoted to these important questions about how cognitive-behavior therapy works. Indeed, these questions have assumed increased importance in light of the striking and widely documented success of this mode of therapy.

## HUMANISTIC-EXPERIENTIAL THERAPIES

The **humanistic-experiential therapies** emerged as significant treatment approaches during the post–World War II era. To a large extent, they developed in reaction to the psychodynamic and behavioral perspectives, which many feel do not accurately take into account either the existential problems or the full potentialities of human beings. In a society dominated by self-interest, mechanization, computerization, mass deception, and "mindless" bureaucracy, proponents of the humanistic-experiential therapies see psychopathology as stemming in many cases from problems of alienation, depersonalization, loneliness, and a failure to find meaning and genuine fulfillment. Problems of this sort, it is held, are not likely to be solved either by delving into forgotten memories or by correcting specific responses.

The humanistic-experiential therapies follow some variant of the general humanistic and existential perspectives outlined in Chapter 3. They are based on the assumption that we have both the freedom and the responsibility to control our own behavior—that we can reflect on our problems, make choices, and take positive action. Whereas some behavior therapists see themselves as "behavior engineers," responsible for changing specific behaviors they deem problematic by appropriate modifications in a person's environment, humanistic-experiential therapists feel that a client must take most of the responsibility for the direction and success of therapy, with a therapist merely serving as counselor, guide, and facilitator. These therapies may be carried out with individual clients or with groups of clients (see HIGHLIGHT 17.5). Although differing among themselves in details, the central focus of humanistic-experiential therapies is always that of expanding a client's "awareness"; accordingly, we consider them Type C (cognition-oriented) approaches.

### Client-Centered Therapy

The **client-centered (person-centered) therapy** of Carl Rogers (1951, 1961, 1966) actually antedated the strong movement toward behavior therapy that began in the 1950s and the "humanistic revolution" of the 1960s. It was developed in the 1940s as a truly innovative alternative to psychoanalysis, the only major psychotherapy of the time.

Rogers rejected both Freud's view of the primacy of irrational instinct and of the therapist's role as prober, interpreter, and director of the therapeutic process. Instead, believing in the natural power of an organism to heal itself, he saw psychotherapy as a process of removing the constraints and hobbling restrictions that often prevent this process from operating. These constraints, he believed, grow out of unrealistic demands that people tend to place on themselves when they believe, as a condition of self-worth, that they should not have certain kinds of feelings, such as hostility. By denying that they do in fact have such feelings, they become unaware of their actual "gut" reactions. As they lose touch with their own genuine experience, the result is lowered integration, impaired personal relationships, and various forms of maladjustment.

The primary objective of Rogerian therapy is to resolve this incongruence—to help clients become able to accept and be themselves. To this end, client-centered therapists establish a psychological climate in which clients can feel unconditionally accepted, understood, and valued as people. In this climate they can begin to feel free for perhaps the first time to explore their real feelings and thoughts and to accept hates and angers and "ugly feelings" as parts of themselves. As their self-concept becomes more congruent with their actual experiencing, they become more self-accepting and more open to new experience and new perspectives; in short, they become better-integrated people.

In client-centered therapy, also called ***nondirective therapy***, it is not the therapist's task to direct the course of therapy. Thus a therapist does not give answers or interpret what a client says or probe for unconscious conflicts or even steer the client onto certain topics. Rather he or she simply listens attentively and acceptingly to what the client wants to talk about, interrupting only to restate in other words what the client is saying. Such restatements, without any judgment or interpretation by the therapist, help the client clarify further the feelings and ideas that he or she is exploring—really to look at

17.5

## Group Therapy

The treatment of clients in groups first received impetus in the military during World War II, when psychotherapists were in short supply. Group therapy was found to be effective in dealing with a variety of problems, and it rapidly became an important therapeutic approach in civilian life. In fact, all the major systematic approaches to psychotherapy that we have discussed—psychoanalysis, behavior therapy, and so on—have been applied in group as well as individual settings.

Group therapy has traditionally involved a relatively small group of clients in a clinic or hospital setting, using a variety of procedures depending on the age, needs, and potentialities of the clients and the orientation of the therapists. The degree of structure and of client participation in the group process varies in different types of groups. Most often, groups are informal, and many follow the format of encounter groups. Occasionally, however, more or less formal lectures and visual materials are presented to clients as a group. For example, a group of alcoholic clients may be shown a film depicting the detrimental effects of excessive drinking on the human body, with a group discussion afterward. Although this approach by itself has not proven effective in combating alcoholism, it is often a useful adjunct to other forms of group therapy.

An interesting form of group therapy is psychodrama, based on role-playing techniques. A client, assisted by staff members or other clients, is encouraged to act out problem situations in a theater-like setting. This technique frees the individual to express anxieties and hostilities or relive traumatic experiences in a situation that simulates real life but is more sheltered. The goal is to help the client achieve emotional catharsis, increased understanding, and improved interpersonal competencies. This form of therapy, developed initially by Moreno (1959), has proved beneficial for the clients who make up the "audience" as well as for those who participate on the "stage" (Sundberg & Tyler, 1962; Yablonsky, 1975).

Group therapy may also be almost completely unstructured, as in activity groups where children with emotional problems are allowed to act out their aggressions in the safety and control of the group setting.

In a recent review of group therapy research, Bednar and Kaul (1994) concluded that the field is in need of more penetrating observations regarding the processes central to group treatment, which might in turn lead to more productive conceptualizations about what, uniquely, group therapies might offer in the domain of mental health treatment.

them and acknowledge them. The following excerpt from a counselor's second interview with a young woman will serve to illustrate these techniques of reflection and clarification:

> Alice: I was thinking about this business of standards. I somehow developed a sort of a knack, I guess, of—well—habit—of trying to make people feel at ease around me, or to make things go along smoothly. . . .
>
> Counselor: In other words, what you did was always in the direction of trying to keep things smooth and to make other people feel better and to smooth the situation.
>
> Alice: Yes. I think that's what it was. Now the reason why I did it probably was—I mean, not that I was a good little Samaritan going around making other people happy, but that was probably the role that felt easiest for me to play. I'd been doing it around home so much. I just didn't stand up for my own convictions, until I don't know whether I have any convictions to stand up for.
>
> Counselor: You feel that for a long time you've been playing the role of kind of smoothing out the frictions or differences or what not.
>
> Alice: M-hm.
>
> Counselor: Rather than having any opinion or reaction of your own in the situation. Is that it?
>
> Alice: That's it. Or that I haven't been really honestly being myself, or actually knowing what my real self is, and that I've been just playing a sort of a false role. Whatever role no one else was playing, and that needed to be played at the time, I'd try to fill it in. (Rogers, 1951, pp. 152–53)

In a survey of trends in psychotherapy and counseling, Rogers was rated one of the most influential psychotherapists among clinical practitioners (Smith, 1982). In addition to his influence in clinical settings, Rogers was a pioneer in attempting to carry out empirical research on psychotherapy. Using recordings of therapy sessions, he was later able to make objective analyses of what was said, of the client-counselor relationships, and of the ongoing processes in these therapy sessions. He was also able to compare a client's behavior and attitudes at different stages of therapy. These comparisons revealed a typical sequence: Early sessions were dominated by negative feelings and discouragement. Then, after a time, tentative statements of hope and greater self-acceptance began to appear. Eventually, positive feelings, a reaching out toward others, greater self-confidence, and interest in future plans appeared. This characteristic sequence gave support to Rogers's hypothesis that, once freed to do so, individuals have the capacity to lead themselves to psychological health.

Pure client-centered psychotherapy, as originally practiced, is rarely used today. It did, however, open the way for a variety of humanistically oriented therapies in which the focus is a client's present conscious problems and in which it is assumed that the client is the primary actor in the curative process, with the therapist essentially being a facilitator. The newer humanistic therapies thus accept Rogers's concept of an active self, capable of sound value choices; they also emphasize the importance of a high degree of empathy, warmth, and unconditional positive regard from the therapist. They differ from original client-centered therapy in having found various shortcuts by which the therapist, going beyond simple reflection and clarification, can hasten and help focus the client's search for wholeness. Such a therapist might, for example, directly confront a client's deceitful mode of self-presentation. It is still the client's search and the client's insights that are seen as central in therapy, however.

## Existential Therapy

Several important concepts underlie **existential psychotherapy.** The existentialist perspective, like the client-centered, emphasizes the importance of the human situation *as perceived by an individual.* The focus is thus on the person's own phenomenologic experience rather than on any notion of objective reality, being in this respect a forerunner of so-called postmodern thought. Existentialists are deeply concerned about the predicament of humankind, the breakdown of traditional faith, the alienation and depersonalization of individuals in contemporary society, and the lack of meaning in people's lives. They see people, however, as having a high degree of freedom and thus as capable both of doing something about their predicament and of being responsible for doing the best they can. The unique ability of human beings to be aware of their mortality and to reflect on and question their existence confronts them with the responsibility for *being*—for deciding what kind of person to become within the constraint of a single lifetime, for establishing their own values, and for actualizing their potentialities.

Existential therapists do not follow any rigidly prescribed procedures, but emphasize the uniqueness of each individual and his or her "way of being in the world." They stress the importance of being aware of one's own existence—challenging an individual directly with questions concerning the meaning and purpose of existence—and of the therapeutic encounter—the complex relationship established between two interacting human beings in the therapeutic situation as they both try to be open and "authentic." In contrast to both psychoanalysis and behavior therapy, existential therapy calls for therapists to share themselves—their feelings, their values, and their own existence.

Besides being authentic themselves, it is the task of existential therapists to keep a client responding authentically to the inescapable intersubjectivity of relations with others (Havens, 1974; May, 1969). For example, if a client says, "I hate you just like I hated my father," a therapist might respond by saying, "I am not your father, I am me, and you have to deal with me as Dr. S., not as your father." The focus is on the here and now—on what a person is choosing to do, and therefore to be, at this moment. This sense of immediacy, of the urgency of experience, is the touchstone of existential therapy and sets the stage for the individual to clarify and choose between alternative ways of being.

With what types of clients and which clinical problems does existential therapy work best? Like classical psychoanalytic therapy, existential psychotherapy is directed primarily toward intelligent and verbal people who appear to be having existential crises. The existential treatment approach is believed to work best with individuals who have anxiety-based disorders or personality disorders rather than psychoses. The following case illustrates the type of problem situation that would lend itself to treatment in the existential framework:

A 42-year-old business executive seeks therapy because he feels that life has lost its meaning—he no longer feels that family matters are important to him (his wife is busy starting her career and his only child recently got married and moved to Alaska). Additionally, his work, at which he has had extraordinary success—earning him both financial security and respect—no longer holds meaning for him. He views his days as "wasted and worthless"—he feels both "bored and panicked"—and he goes through the motions of the business day feeling "numb," as though he isn't even there. At times, he feels fearful and overwhelmed with a sense of dread that this is all that life has left for him.

## Gestalt Therapy

The term *gestalt* means "whole," and **gestalt therapy** emphasizes the unity of mind and body—placing strong emphasis on the need to integrate thought, feeling, and action. Gestalt therapy was developed by Frederick (Fritz) Perls (1967, 1969) as a means of teaching clients to recognize the bodily processes and emotions they had been blocking off from awareness. As with the client-centered and existential approaches, the main goal of gestalt therapy is to increase an individual's self-awareness and self-acceptance.

Although gestalt therapy is commonly used in a group setting, the emphasis is on one person at a time with whom a therapist works intensively, attempting to help identify aspects of the individual's self or world that are not being acknowledged in awareness. The individual may be asked to act out fantasies concerning feelings and conflicts, or to "be" one part of a conflict while sitting in one chair and then switch chairs to take the part of the "adversary." Often the therapist or other group members will ask questions like, "What are you aware of in your body now?" or "What does it feel like in your gut when you think of that?"

In Perls's approach to therapy, a good deal of emphasis is also placed on dreams, but with an emphasis very different from that of classical psychoanalysis. In gestalt theory, every element of a dream, including seemingly inconsequential, impersonal objects, are considered to be representations of unacknowledged aspects of the dreamer's self. The therapist urges the client to suspend normal critical judgment and to "be" the object in the dream, reporting then on the experience. For example, Perls asked a middle-aged woman who had dreamed of a lake to "be" the lake, with the following result:

> "I'm a lake . . . I'm drying up, and disappearing, soaking into the earth . . . (with a touch of surprise) dying. . . . But when I soak into the earth, I become a part of the earth—so maybe I water the surrounding area, so . . . even in the lake, even in my bed, flowers can grow (sighs). . . . New life can grow . . . from me (cries). . . . (sadly, but with conviction) I can paint—I can create—I can create beauty. I can no longer reproduce. . . . but I . . . I'm . . . I . . . keep wanting to say I'm food . . . I . . . as water becomes . . . I water the earth, and give life-growing things, the water—they need both the earth and water, and the . . . and the air and the sun, but as the water from the lake, I can play a part in something, and producing—feeding." (Perls, 1969, pp. 81–82)

In gestalt therapy sessions, the focus is on the more obvious elements of a person's behavior. Such sessions are often called "gestalt awareness training" because the therapeutic results of the experience stem from the process of becoming more aware of one's total self and environment. The technique of working through unresolved conflicts is called "taking care of unfinished business." We all go through life, according to Perls, with unfinished or unresolved traumas and conflicts. We carry the excess baggage of these unfinished situations into new relationships and tend to reenact them in our relations with other people. If we are able to complete our past unfinished business, we then have less psychological tension to cope with and can be more realistically aware of ourselves and our world.

Expressing themselves in front of the group, perhaps taking the part of first one and then another fragment of a scene, and denied the use of their usual techniques for avoiding self-awareness, clients are brought to an "impasse," at which point they must confront their feelings and conflicts. According to Perls, "In the safe emergency of the therapeutic situation, the neurotic discovers that the world does not fall to pieces if he or she gets angry, sexy, joyous, mournful" (1967, p. 331). Thus clients find that they can, after all, get beyond impasses on their own.

## Evaluation of the Humanistic-Experiential Therapies

The humanistic-experiential therapies have been criticized for their lack of highly systematized models of human behavior and its specific aberrations, their lack of agreed-upon therapeutic procedures, and their vagueness about what is supposed to happen between client and therapist. These very features, however, are seen by many proponents of this general approach as contributing to its strength and vitality. Systematized theories can reduce individuals to abstractions, which can diminish their perceived worth and deny their uniqueness. Because people are so different, we should expect that different techniques are appropriate for different cases. Rigorous research on the outcomes produced by the humanistic-existential therapies is rare, but some has been carried out on the gestalt variety. This technique has a respectable, though unspectacular, record (Smith et al., 1980).

In any event, many of the humanistic-experiential concepts—the uniqueness of each individual, the satisfaction that comes from developing and using one's potentials, the importance of the search for meaning and fulfillment, and the human power for choice and self-direction—have had a major impact on our contemporary views of both human nature and psychotherapy.

# THERAPY FOR INTERPERSONAL RELATIONSHIPS

In Chapter 3, we noted the interpersonal perspective's emphasis on the role of faulty communications, interactions, and relationships in maladaptive behavior. This viewpoint has had an important impact on approaches to therapy—particularly, as we have seen, on contemporary psychodynamic therapy (e.g., Horowitz, Rosenberg, & Bartholomew, 1993; Strupp, 1993) but also in the behavioral, humanistic, and existential therapies. For example, in behavior and cognitive-behavior therapy we have seen a notable rise in concern with the client-therapist relationship and a growing emphasis on modifying social reinforcements that may be maintaining maladaptive responses; in humanistic and existential therapies we have seen the focus on such problems as lack of acceptance, relatedness, and love in a person's life. Important new therapies for the Axis II personality disorders, such as those of Benjamin (1993) and of Linehan (1993), strongly emphasize the client-therapist interpersonal relationship as a dominant vehicle for bringing about constructive change.

Although the interpersonal perspective is increasingly seen as essential to fully understanding many types of "individual" disorder, many problems brought to practitioners are explicitly relationship problems. That is, the presenting complaint is not so much one of dissatisfaction with self or one's own behavior as one of inability to achieve satisfactory accords with others. A common example is couples' or marital distress. The maladaptive behavior is in these instances shared between the members of the relationship; it is, to use the contemporary term, "systemic" (Gurman, Kniskern, & Pinsof, 1986). Such problems require therapeutic techniques that focus on relationships as much as or more than on individuals. As was seen in Chapter 11, many problems presenting as individual sexual dysfunctions turn out to be systemic in character. In this section, we will explore the growing fields of couples and family therapy as examples of this type of multiple-client intervention. In general, these therapies, when placed in the context of helping individuals to change, focus on altering the reactions of the interpersonal environment to the behavior of each involved person. To this extent, they may be considered chiefly Type E approaches.

It is important to note that couples and family therapies can be and are conducted from any of the perspectives discussed in this chapter and in Chapter 3 (see Alexander, Holtzworth-Munroe, & Jameson's [1994] review for examples). Thus behavioral marital therapy, often utilizing a contracting approach, is one of several widely available variations on the theme.

## Couples Counseling (Marital Therapy)

The large numbers of couples seeking assistance with relationship problems have made couples counseling a growing field of therapy. Typically the partners are seen together, and therapy focuses on clarifying and improving their interactions and relationships. Therapy for only one of the partners has proved less effective for resolving such problems (Gurman & Kniskern, 1978), although it is quite routine at the start of couples therapy for each partner secretly to harbor the wish that only the other will have to do the changing (e.g., Cordova & Jacobson, 1993). It is almost always necessary, however, that both partners alter their reactions to the other.

**Couples counseling,** or **marital therapy,** includes a wide range of concepts and procedures.

*Treatment of the entire family may be desirable where abnormal behavior patterns in individuals are maintained by family dynamics.*

Most therapists emphasize mutual need gratification, social role expectations, communication patterns, and similar interpersonal factors. Not surprisingly, happily married couples tend to differ from unhappily married couples in that they remain good friends, talk more to each other, keep channels of communication open, make more use of nonverbal communication, and show more sensitivity to each other's feelings and needs. For example, in a study comparing distressed versus nondistressed couples, Margolin and Wampold (1981) found that nondistressed couples showed more problem-solving behavior than distressed couples, a result found often in studies of this sort. The extremely common scenario, "He never talks to me, he withdraws" versus "All she ever does is bitch and complain, so who needs to talk," is one whose resolution obviously calls for considerable problem-solving skill, not to mention a degree of maturity and patience in employing it.

Faulty role expectations often play havoc with marital adjustment. For example, Paul (1971) cited the case of a couple who came for marital therapy when the 39-year-old husband was about to divorce his wife to marry a much younger woman. During therapy, he broke into sobs of grief as he recalled the death of his Aunt Anna, who had always accepted him as he was and created an atmosphere of peace and contentment. In reviewing this incident, the husband realized that his girlfriend represented his lifelong search for another Aunt Anna. This led to a reconciliation with his wife, who was now more understanding of his needs, feelings, and role expectations and thus altered her behavior toward her husband accordingly.

One of the difficulties in couples therapy is the intense emotional involvement of the partners, which makes it difficult for them to perceive and accept the realities of their relationship. Often wives can see clearly what is "wrong" with their husbands but not what attitudes and behaviors of their own are contributing to the relationship, while husbands tend to have remarkable "insight" into their wives' flaws but not their own. To help correct this problem, videotape recordings have been used increasingly to recapture crucial moments of intense interaction between the partners. By watching playbacks of these tapes after immediate tensions have diminished, the partners can gain a fuller awareness of the nature of their interactions. Thus a husband may realize for the first time that he tries to dominate rather than listen to his wife and consider her needs and expectations, or a wife may realize that she is continually undermining her husband's feelings of worth and esteem. The following statement was made by a young wife after viewing a videotape playback of the couple's first therapy session:

> "See! There it is—loud and clear! As usual you didn't let me express my feelings or opinions, you just interrupted me with your own. You're always telling me what I think without asking me what I think. And I can see what I have been doing in response—withdrawing into silence. I

feel like, what's the use of talking." In achieving this shared insight about a dominant pattern in their interactions, the couple was able to work out a much more satisfactory marital relationship within a few months.

Other relatively new and innovative approaches to couples therapy include training the partners to use Rogerian nondirective techniques in listening to each other and helping each other clarify and verbalize their feelings and reactions. A mutual readiness to really listen and try to understand what the other is experiencing—and an acceptance of whatever comes out in this process—can be both therapeutic for the individuals and productive of a more open and honest relationship in the future.

Behavioral therapy has also been used to bring about desired changes in marital relationships. The partners, for example, may be taught to reinforce instances of desired behavior while withdrawing reinforcement for undesired behavior. In a study comparing behavioral with insight-oriented psychodynamic marital therapy, neither proved superior to the other, but both significantly outperformed a waiting-list control condition (Snyder & Wills, 1989).

How effective in general are couples therapies at resolving relationship crises and promoting more effective marriages or intimate partnerships? One study involved a five-year follow-up of 320 former marital therapy clients and compared their divorce rates with those of the general population (Cookerly, 1980). In cases in which both partners underwent therapy together, 56.4 percent had remained married for the five-year period; in cases in which other types of therapy were used, 29 percent had remained married. All forms of therapy were associated with significantly better results in resolving marital crises and keeping marriages together than was the use of no therapy at all. This conclusion is also supported in Gurman and colleagues' (1986) more recent review of numerous outcome studies. Finally, couples therapy has been successfully used as an adjunct in the treatment of individual problems, such as depression, phobias, and alcohol abuse (Alexander et al., 1994; Jacobson, Holtzworth-Munroe, & Schmaling, 1989; Shadish et al., 1993).

Of course, a motivational factor in outcome assessments of this sort makes interpretation somewhat difficult. People strongly motivated to stay in their relationships are more likely to give couples therapy a serious try than their less motivated counterparts. Such motivation may itself, irrespective of therapy, make for partnership longevity or, perhaps, tolerance of partner abnormality. On the other hand, as we have seen, strong motivation is a key element in the likely success of any psychological therapy, so the research on outcomes of couples therapy has a certain face validity even acknowledging some unclarity about the role of motivational variations.

## Family Therapy

Therapy for a family group overlaps with couples and marital therapy but has somewhat different roots. Whereas marital therapy developed in response to the large number of clients who came for assistance with couples' problems, family therapy began with the finding that many people who had shown marked improvement in individual therapy—often in institutional settings—had a relapse on their return home. It soon became apparent that many of these people came from disturbed family settings that required modification if they were to maintain their gains. A pioneer in the field of family therapy has described the problem as follows:

> Psychopathology in the individual is a product of the way he deals with his intimate relations, the way they deal with him, and the way other family members involve him in their relations with each other. Further, the appearance of symptomatic behavior in an individual is necessary for the continued function of a particular family system. Therefore, changes in the individual can occur only if the family system changes. . . . (Haley, 1962, p. 70)

This viewpoint led to an important concept in the field of psychotherapy, namely, that the problem or disorder shown by an "identified client" is often only a symptom of a larger family problem. A careful study of the family of a disturbed child, for example, may reveal that the child is merely reflecting the pathology of the family unit. As a result, most family therapists share the view that the family—not simply the designated "client"—must be directly involved in therapy if lasting improvement is to be achieved. This is a conclusion also implied in our pathogenic loop model described earlier. Its application is increasingly seen in attempts to understand relapse after recovery from even severe disorder, as in the work on expressed emotion (EE) in mood disorders and schizophrenia (see Chapters 6 and 12).

Perhaps the most widely used approach to family therapy is the "conjoint family therapy" of Satir (1967). Her emphasis is on improving faulty communications, interactions, and relationships among family members and on fostering a family system that better meets the needs of each member. The following example shows Satir's emphasis on the problem of faulty communication:

> Husband: She never comes up to me and kisses me. I am always the one to make the overtures.
>
> Therapist: Is this the way you see yourself behaving with your husband?
>
> Wife: Yes, I would say he is the demonstrative one. I didn't know he wanted me to make the overtures.
>
> Th: Have you told your wife that you would like this from her—more open demonstration of affection?
>
> H: Well, no you'd think she'd know.
>
> W: No, how would I know? You always said you didn't like aggressive women.
>
> H: I don't, I don't like dominating women.
>
> W: Well, I thought you meant women who make the overtures. How am I to know what you want?
>
> Th: You'd have a better idea if he had been able to tell you. (Satir, 1967, pp. 72–73)

Another encouraging approach to resolving family disturbances is called **structural family therapy** (Minuchin, 1974). This approach, based on "systems theory," assumes that a family system itself is more influential than individual personality or intrapsychic conflicts in producing abnormal behavior. It assumes that the family system has contributed to the characteristic behaviors that individual family members have developed; if the family context changes, then the individual members will have altered experiences in the family and will behave differently in accordance with the changed requirements of the new family context. Thus an important goal of structural family therapy is to change the organization of the family in such a way that the family members will behave more positively and supportively toward each other.

Structural family therapy is focused on present interactions and requires an active but not directive approach on the part of a therapist. Initially, the therapist gathers information about the family—a "structural map" of the typical family interaction patterns—by acting like one of the family and participating in the family interactions as an insider. In this way, the therapist discovers whether the family system has rigid or flexible boundaries, who dominates the power structure, who gets blamed when things go wrong, and so on.

*Both partners typically participate in couples counseling or marital therapy.*

Armed with this understanding, the therapist then uses himself or herself as a change medium for altering the interaction among the members. For example, Aponte and Hoffman (1973) reported the successful use of structural family therapy in treating an anorexic 14-year-old girl:

> Analyzing the communications in the family, the therapists saw a competitive struggle for the father's attention and observed that the girl, Laura, was able to succeed in this competition and get "cuddly" attention from her father by not eating. To bring the hidden dynamics out into the open, they worked at getting the family members to express their desires more directly—in words instead of through cryptic behavioral messages. In time, Laura became much more able to verbalize her wishes for affection and gave up the unacceptable and dangerous method of not eating.

Structural family therapy has also been used successfully in the treatment of bulimia (Schwartz, Barrett, & Saba, 1983), childhood psychosomatic disorders (Minuchin et al., 1975), and narcotic addiction (Stanton & Todd, 1976).

As with couples problems, maladaptive family relationships have also been successfully overcome by behaviorally oriented therapies. With this type of therapy, Huff (1969) has suggested that the therapist's task is to reduce the aversive value of the family for the identified client as well as that of the client for other family members. "The therapist does this by actively manipulating the relationship between members so that the relationship changes to a more positively reinforcing and reciprocal one" (p. 26).

After reviewing family therapy approaches, Gurman and Kniskern (1978) concluded that structural family therapy had had more impressive results than most other experientially and analytically oriented approaches they had reviewed. By the time of their subsequent review eight years later (Gurman et al., 1986), the conclusion had shifted somewhat to favor behavioral intervention. A recent quantitative review by Shadish and colleagues (1993) supports the latter conclusion.

## THE INTEGRATION OF THERAPY APPROACHES

Although an integration of psychoanalysis and learning theory was attempted as early as 1950 by Dollard and Miller in their *Personality and Psychotherapy*, the two treatment approaches diverged significantly in the 1960s and 1970s as the learning-based behavioral therapies began to assert themselves. Recently, a great deal has been written about the possibility of gaining a rapprochement between behavior therapy and other schools of therapy, particularly psychodynamic therapy (Arkowitz & Messer, 1984; Goldfried, Greenberg, & Marmar, 1990; Marmor & Woods, 1980; Norcross & Goldfried, 1992; Wachtel, 1977, 1982). At first, this trend may seem surprising, given the generally competitive atmosphere and the critical struggles that have traditionally existed between psychoanalysts and behavior therapists. Early behaviorists were adamant in their criticism of psychoanalysis as inefficient and mystical. The analysts reacted with strong counterarguments, partly in their own defense but also in keeping with their belief that behavioral therapies were superficial and treated only symptoms, while psychoanalytic treatments sought "deeper" and more permanent cures.

Over the years, however, behavioral and psychoanalytic proponents have had time to become accustomed (or perhaps "desensitized") to each other's criticisms. With the wide dissemination and practice of behavioral methods, it has become apparent to some psychodynamically oriented therapists that behavioral methods are quite effective in the treatment of many disorders. Similarly, many behaviorally oriented therapists have concluded that it is not simply the application of a *technique* that brings about change in a client. They acknowledge that "relationship" factors are exceedingly important even when rigorous behavior modification procedures are being used (Lazarus, 1981, 1985). In addition, research comparing both treatment methods has generally shown that neither approach has been demonstrated invariably to be superior to the other (Sloane et al., 1975), although, overall, there seems to be a small but consistent advantage for behavioral and cognitive-behavioral methods (Dobson, 1989; Engels et al., 1993; Lambert & Bergin, 1994; Miller & Berman, 1983; Shadish et al., 1993; Smith et al., 1980).

Kendall (1982b) has concisely summarized the reasons for the current interest in integrating behavior therapy with other methods. He noted that (a) some behaviorists have concluded that the human organism is multifaceted and that focusing only on "behavior" is not sufficient as a treatment goal; (b) the "less than perfect" success of available therapy methods justifies combining the most successful treatment strategies from all approaches; (c) integrating diverse therapies might inspire a new enthusiasm and promote novel applications of varied treatment methods and perhaps promote new formulations of old problems; and (d) integrating diverse therapy schools would require members of a given school to begin to question the assumptions underlying their treatment approaches and would promote a broad reappraisal from different perspectives. A similar argument has been made more recently by Robins and Hayes (1993) in regard to the need for cognitive therapies to remain open to contributions from other approaches. Our own "loop" model is, of course, completely in accord with this perspective.

According to Kendall, however, inherent problems face the integrationist position. First, no common language unites the various therapy schools. Second, it is much easier for a trainee to learn a single therapeutic approach than to learn elements of various approaches. Finally, basic conceptual differences exist that would preclude a fully satisfactory merger between behavior therapy and psychodynamic therapy, such as their different emphases on etiological factors, treatment goals, and methods.

Further examination of therapeutic methods from the vantage point of alternative views may, in time, lead to interestingly amalgamated psychosocial therapies. It does not appear at this point, however, that many of the advocates of the various positions will be able to put aside their long identification with particular schools and easily assimilate alien notions and practices, notwithstanding a common self-description among therapists as "eclectic."

Meanwhile, an equally if not more vexing problem concerns the integration of psychosocial and biological forms of treatment. As shown in earlier chapters, combined treatment of this sort, where it has been tried, has often proved to be more effective than either alone. In this area we confront not only philosophical differences but interdisciplinary political and economic ones as well. Although there is a developing movement among a segment of clinical psychologists, endorsed to a degree by the American Psychological Association, to seek prescription-writing privileges that would permit them to administer psychoactive drugs (strongly opposed by organized medicine and psychiatry), as of this writing the overwhelming majority of nonmedical therapists may not legally do so. Even among clinical psychologists, many are opposed to this trend, mostly out of concern that easy access to drug treatment will corrupt the further and much needed development of even more powerful forms of psychosocial intervention.

In our judgment, the latter concern has merit; too frequently, we have seen the clinical process distorted by hasty and exclusive recourse to what is usually, at best, palliative medication. Still, judicious combined treatment surely has much to recommend it for certain types of disorder (Klerman et al., 1994), and it is inconvenient, typically more costly, and potentially involves enhanced risks for pharmacologic and psychosocial treatment of the same client to be managed by different practitioners. It will be interesting to see how this issue is played out by the mental health professions in the coming years.

# THE EVALUATION OF SUCCESS IN PSYCHOTHERAPY

Competition between the various "brands" of therapies has tended to obscure the actual successes of psychosocial treatment. Four and a half decades ago, Hans Eysenck (1952), a well-known British psychologist, shook the field by concluding in his review of evidence on treatment outcomes that people who were untreated or simply placed on a waiting list for psychotherapy improved about as much as those who received therapy. This pronouncement prompted a flurry of research activity and a thorough reanalysis of the existing data. Reevaluation of therapy-outcome research accomplished before Eysenck's review, as well as a great deal done since, has painted a different and far more positive picture of the overall effectiveness of psychotherapy (Lambert & Bergin, 1994).

## Problems of Evaluation

Evaluating the effectiveness of psychological treatment is a difficult enterprise for several reasons. At best, it is an inexact process, dependent on imperfect measurement and outcome data. For example, attempts at evaluation generally depend on one or more of the following sources of information: (a) a therapist's impression of changes that have occurred, (b) a client's reports of change, (c) reports from the client's family or friends, (d) comparison of pretreatment and posttreatment personality test scores, and (e) measures of change in selected overt behaviors.

Unfortunately, each of these sources has serious limitations. A therapist may not be the best judge of a client's progress, since any therapist is likely to be biased in favor of seeing himself or herself as competent and successful. Furthermore, therapists can inflate improvement averages by consciously or unconsciously encouraging difficult clients to discontinue therapy. The problem of how to manage "dropouts" complicates most therapy-outcome studies (for example, are they to be counted as "failures" when in fact they receive little or none of the therapy being evaluated?). It has also been somewhat facetiously remarked that a therapist often thinks a client is getting better because he or she is getting accustomed to the client's symptoms.

A client, also, is an unreliable source concerning the outcomes of therapy. Clients may not only want to think that they are getting better for personal reasons, but they may report that they are being helped in an attempt to please the therapist. In addition, because therapy often requires a considerable investment of time, money, and sometimes emotional distress, the idea that it is useless is a dissonant one. Family and relatives may also be inclined to "see" the improvement they had hoped for, although they often seem to be more realistic than either the therapist or the client in their long-term evaluations.

Outside clinical ratings by an independent observer are sometimes used in psychotherapy-outcome research to evaluate the progress of a client; these may be more objective than ratings by those directly involved in the therapy. Another widely used objective measure of client change is performance on psychological tests. A client evaluated in this way takes a battery of tests before and after therapy and the differences in scores are assumed to reflect progress or deterioration. Although such tests may indeed show changes, these may sometimes be artifactual, as with ***regression to the mean*** phenomena (Speer, 1992), where very high (or low) scores tend on repeated measurement to drift toward the average of their own distributions—yielding a false impression that some real change has been documented. Also, the particular tests chosen are likely to focus on the theoretical predictions of the therapist or researcher. They are not necessarily valid predictors of how the client will behave in real life, nor can they give any indication of whether the changes that have occurred are likely to be enduring. Concerning the latter point, however, there is now abundant evidence from long-term follow-up that the effects of psychotherapy in general, as variously measured, are decidedly not ephemeral or temporary (e.g., Lambert & Bergin, 1994; Nicholson & Berman, 1983).

Changes in preselected and specifically denoted behaviors appear to be the safest measures of outcome, especially where the occurrence of these outside the therapy situation itself is systematically monitored. Such techniques, including client self-monitoring, have been widely and effectively used, especially by behavior therapists. Generalized terms such as ***recovery, marked improvement,*** and ***moderate improvement,*** as applied to initially problematic behavior and often used in outcome research, are open to considerable differences in interpretation. In addition, even under the best of circumstances there is always the possibility that improvement will be attributed to the particular form of treatment used, when it is in fact a product of other events in a client's life or even of "spontaneous" change.

In spite of these difficulties, however, it is to at least some extent possible to study the effectiveness of various treatment approaches separately—determining what procedures work best with various types of individuals (Kendall & Norton-Ford, 1982; Smith et al., 1980). In the course of our discussion of abnormal behavior patterns, we have mentioned a number of such studies, most of which have demonstrated positive outcomes from psychotherapy.

In this context, it is pertinent to ask what happens to people who do not obtain formal treatment. In view of the many ways that people can help each other, it is not surprising that often considerable improvement occurs without professional therapeutic intervention. Relevant here is the observation that treatment offered by professional therapists has not, in general, been clearly demonstrated to be superior in outcome to nonprofessionally administered therapies (Christensen & Jacobson, 1994). Also, some forms of psychopathology, such as manic and depressive episodes and some instances of schizophrenia, appear to run a fairly brief course with or without treatment, and there are many other instances in which disturbed people improve over time for reasons that are not apparent.

Nevertheless, even if many emotionally disturbed persons tend to improve over time without psychotherapy, it seems clear that psychotherapy can often accelerate improvement or ensure desired behavior change that might not otherwise occur (Lambert & Bergin, 1994; Telch, 1981). Most researchers today would agree that psychotherapy is more effective than no treatment, and indeed the pertinent evidence, widely cited throughout this chapter and the entire text, is strongly confirmatory. The chances of an "average" client benefiting significantly from psychological treatment are, overall, impressive (Lambert & Bergin, 1994).

Furthermore, improvement seems a function of the number of therapy sessions undertaken—with the largest gains achieved early (that is, within six months) in the therapeutic relationship (Howard et al., 1986). Very long-term psychotherapy is actually quite rare, but such cases tend to create the impression, even among professionals, that disordered behavior is more intractable than for the most part it actually is. In one study of this problem (Howard et al., 1989), 56 percent of the total therapy sessions offered by a clinic were "consumed" by only 16 percent of the clients.

Nonetheless, the issue of treatment evaluation remains vital—both ethically and practically—if psychologists and other mental health personnel are to be justified in intervening in other people's lives. The issue becomes especially vital in light of evidence that some clients are ***harmed*** in their encounters with psychotherapists (Lambert & Bergin, 1994; Mays & Franks, 1985; Strupp, Hadley, & Gomes-Schwartz, 1977). This problem of negative effects, which many therapists acknowledge when directly queried (see Appendix C, pp. 223–343, of the Strupp et al. [1977] volume for interesting first-person accounts), is addressed further in the "Unresolved Issues" section.

Finally, we must note some problems in the growing trend for varied psychological treatments to be directly compared, within the same study, with the outcomes of biological treatments, usually drug therapies. Although such studies have frequently reported the "superiority" of one or the other of these therapy types in the treatment of various disorders, we remain skeptical that a truly definitive comparison of the outcomes of the two forms of therapy is ultimately possible. In fact, it is not clear that a completely valid outcome study can be done with psychosocial treatment when the design of the study adheres to established modes of evaluating the efficacy of drugs, as most by custom do. As Stiles and Shapiro (1989) have pointed out in a detailed examination of the issues involved, psychotherapy and drug therapy differ on many dimensions of critical importance in deciding on, and in interpreting, issues both of study design and the outcome measures used.

Take, for example, a therapist himself or herself as a variable, including such attributes as experience in treating the particular disorder, interpersonal skill, familiarity with the subcultural background of a client, faith in the treatment, and perhaps even personal attractiveness or charisma as experienced by the client. We have solid reason, based on available research findings, to believe that such things may be of crucial significance in determining the outcome of any psychosocial treatment effort (see Beutler et al., 1994; Lambert & Bergin, 1994). Now contrast this with the typical situation for drug treatment. Here, the "active ingredient" of the treatment is pretty much the same no matter who writes the prescription, and a therapist's personal attributes or his or her experience in treating the disorder (with the possible exception of a nonspecific placebo component) are largely irrelevant. With such important differences that vary in uncontrolled (and probably uncontrollable) ways in psychotherapy versus drug-comparison studies, it is not easy to see how any general and unequivocal conclusions regarding differential effectiveness could be made, almost regardless of the quantitative results obtained.

Precisely this sort of difficulty attends perhaps the best-known and most widely cited study of this sort, the NIMH-sponsored multisite "model" study of the treatment of depression (Elkin et al., 1989). In this study, two psychosocial treatments, cognitive-behavior therapy (CBT) and interpersonal therapy (IPT), were compared with antidepressant drug treatment (imipramine) plus general clinical management (IMIP-CM) and placebo pills plus clinical management (PLA-CM). We note in passing that the supposed "blinding" (with respect to who gets active drug and who gets placebo) for the latter two conditions is rarely successfully achieved (Greenberg et al., 1992). The immediate posttreatment results, in brief, were that the IMIP-CM treatment was slightly superior to CBT and IPT, especially for more severely depressed patients, with the PLA-CM group coming in last but nevertheless significantly benefiting. However, because of a very common design defect (admittedly a difficult one) treatments were confounded with treating personnel, who were in turn confounded with treatment sites. The upshot was a statistically significant interaction of treatments-by-sites (i.e., therapists) in determining patients' clinical outcomes. In other words, the relative outcomes of the several treatments substantially depended on the characteristics of the therapists administering them, a result we would *routinely* predict to the extent that psychosocial therapeutic influence is involved. And, incidentally, the not inconsiderable improvement of PLA-CM patients in the study (recovery rates of 15–40 percent, depending on initial severity) can *only* be attributed to psychosocial or some other unknown influence.

Taking the reported results of this study at face value, then, would entail the *erroneous* conclusion that, in cases of severe depression, antidepressant drugs are the treatment of choice. In fact, the modest reported IMIP-CM overall treatment superiority is on careful examination shown to be true of only one of the three study sites employed, as recently pointed out by Hollon, Shelton, and Davis (1993). The original report (Elkin et al., 1989) notes that CBT therapists at one of the sites, and IPT therapists at another, produced results entirely comparable to those of the overall IMIP-CM treatment condition. We know from another source (O'Malley et al., 1988), indeed, that the IPT therapists used in this study showed widely varying aptitudes for conducting this type of treatment even before the study began. A reasonable conclusion from this study would seem to be that the characteristics of the *therapist,* in relation to the therapy to be employed, are of crucial significance in determining outcomes, perhaps (and somewhat surprisingly) even with respect to drug treatment.

We have examined the above study in some detail only because it illustrates certain problems in psychotherapy outcome research, not because it sheds a great deal of light on the therapy of depression. In fact, a report of an 18-month follow-up of the patients in this study (Shea et al., 1992) is also remarkable for what it does *not* communicate (e.g., gross numbers and percentages and only minimal inferential probability statistics are reported), rather weakly concluding that *none* of the four treatment conditions was sufficiently potent "for most patients to achieve full recovery and lasting remission" (p. 782). We question whether this statement accurately captures the meaning of the results as reported, which are relatively unfavorable to the drug treatment and positive for CBT. However, outcomes in the various available treatments for depression as an issue in itself has been discussed earlier, so we shall dispense with any attempt to address that specific topic here.

## Social Values and Psychotherapy

The criticism has been raised—from both inside and outside the mental health professions—that psychotherapy can be viewed as an attempt to get people adjusted to a "sick" society rather than to encourage them to work toward its improvement. As a consequence, psychotherapy has often been considered the guardian of the status quo. This issue is perhaps easier for us to place in perspective by looking at other cultures. For example, there have been frequent allegations that psychiatry was until recently used as a means of political control in the Soviet Union, an abuse that has now been officially acknowledged (see *Schizophrenia Bulletin,* 1990, v. 16, no. 4). It is encouraging to note that these practices had been all but universally condemned by the international mental health community. Although few people make the claim that psychiatry in the Western world is used to gain control over social critics, there is nevertheless the possibility that therapists are, in some ways, placed in the roles of "gatekeepers" of social values. Such charges, of course, bring us back to the question we raised in Chapter 1: What do we mean by abnormal? Our answer to that question can only be made in the light of our values.

In a broader perspective, of course, we are concerned with the complex and controversial issue of the role of values in science. Psychotherapy is not, or at least should not be, a system of ethics; it is a set of tools to be used at the discretion of a therapist in pursuit of a client's welfare. Thus mental health professionals are confronted with the same kinds of questions that confront scientists in general. Should a physical scientist who helps develop thermonuclear weapons be morally concerned about how they are used? Similarly, should a psychologist or behavioral scientist who develops powerful techniques of behavior control be concerned about how they are used?

Many psychologists and other scientists try to sidestep this issue by insisting that science is value-free—that it is concerned only with gathering "facts," not with how they are applied. Each time therapists decide that one behavior should be eliminated or substituted for another, however, they are making a value choice. The increasing social awareness of today's mental health professionals has brought into sharp focus ethical questions concerning their roles as therapists and value models, as well as their roles as agents for maintaining the status quo or fostering social change. For example, is a therapist to assume the depression of a young homemaker-mother who is abused by a drunken husband to be an internally based disorder requiring "treatment," as once would have been routine? Or does the therapist perhaps not have a larger responsibility to look beyond this individual-pathology viewpoint and confront the abnormality of the marital relationship? Therapy takes place in a context that involves the values of the therapist, the client, and the society in which they live. There are strong pressures on a therapist—from parents, schools, courts, and other social institutions—to help people adjust to "the world as it is." At the same time, there are many counterpressures, particularly from young people who are seeking support in their attempts to become authentic people rather than blind conformists.

The dilemma in which contemporary therapists may find themselves is illustrated by the following case:

A 15-year-old high school sophomore is sent to a therapist because her parents have discovered that she has been having sexual intercourse with her boyfriend. The girl tells the therapist that she thoroughly enjoys such relations and feels no guilt or remorse over her behavior, even though her parents strongly disapprove. In addition, she reports that she is quite aware of the danger of becoming pregnant and is careful to take contraceptive measures.

What is the role of the therapist in such a case? Should the girl be encouraged to conform to her parents' mores and postpone sexual activity until she is older and more mature? Or should the parents be helped to adjust to the pattern of sexual behavior she has chosen? What should be the therapist's goal? As was noted earlier, it is not unusual to find some individuals being referred for psychological treatment because their behavior, not particularly destructive or disturbing, has caused concern among family members who wish the therapist to "fix" them.

It is apparent that there are diametrically opposed ways of dealing with problems in therapy. Society must enforce conformity to certain norms if it is to maintain its organization and survive. But how does one distinguish between norms that are vital for the common good and those that are irrelevant, outmoded, or arbitrarily imposed by thoughtless devotion to a particular subgroup's notion of revealed truth? It is often up to individual therapists to decide what path to take, and this requires value decisions on their part concerning what is best for an individual and for the larger society. Thus a mental health professional is confronted with the problem of "who (or what) controls the controller"; that is, of developing ethical standards and societal safeguards to prevent misuse of the techniques they have developed for modifying individual and group behavior (Lakin, 1991).

## UNRESOLVED ISSUES

### on Psychotherapy

Probably no treatment procedure in medicine or surgery is without risk in the sense of potentially harmful or even fatal effects on a client. Generally speaking, moreover, the more potent the treatment in terms of potential dramatic benefit, the more risky the procedure. The situation appears to be no different with respect to psychotherapy. As we have noted, the outcomes of psychotherapy do not range from neutral (no effect) to positive, but rather seem to encompass a significant negative or deteriorative effect. The extreme is client suicide, although we certainly do not suggest that all such outcomes could be avoided with more skillful psychotherapy. In any event, some client-psychotherapist relationships, approaching perhaps 10 percent (Lambert & Bergin, 1994), apparently result in the client's being worse off than if psychotherapy had never been undertaken.

Our judgment about the gravity of this situation would be less severe if it were taken more seriously among professional psychotherapists than our experience suggests, and if we knew more about how to prevent it. We do have some guidelines about factors that should be considered, based in part on reviews of the issue in books by Mays and Franks (1985) and Strupp and colleagues (1977). We know that clients with certain types of disorders that are notoriously difficult to treat (such as borderline personality disorder) are more likely than others to deteriorate in treatment. We have also known for some time that an overly aggressive, intrusive, abruptly defense-challenging therapeutic style can be dangerous to client functioning, particularly where it is unmodulated by therapist warmth and empathy. Similarly, the concurrent occurrence of uncontrollable negative events (such as divorce) in a client's life outside therapy can obviously interfere with therapeutic progress.

Obvious therapeutic impasses account for only a portion of the failures. In other instances a bewildering network of interactive factors operate together and idiosyncratically in an individual case (for example, the "match" of therapist and client characteristics) to produce deteriorating outcomes. Our impression, supported by some evidence reviewed by Lambert (1989) and Lambert and Bergin (1994), is that certain therapists, probably for reasons of personality, just do not do well with certain types of client problems. In light of these intangible factors, we take it as every therapist's responsibility to monitor his or her work with various types of clients to discover any such deficiencies, and to refer promptly to other therapists those persons with whom one may be ill-equipped to work.

A special case of therapeutic harm is the problem of therapist-client sexual entanglements, typically seduction of a client (or "former" client) by a therapist, which is considered unethical conduct. Given the frequently intense and intimate quality of therapeutic relationships, we should perhaps not be surprised that the issue of sexual attraction arises. In fact, Pope, Sonne, and Holroyd (1993) have recently published a searching, book-length analysis of the problem, together with suggested solutions for dealing with it in an effective and ethical manner. What is astonishing is the apparent frequency with which it is manifested in exploitive and unprofessional behavior on the part of therapists—all the more so in light of the fact that virtually all authorities agree that such liaisons are nearly always destructive of client functioning in the long run.

A variety of evidence, including anonymous admissions of therapists in various surveys over the years, suggests that this source of client abuse and likely negative outcome is by no means rare. A substantial proportion of the complaints received and processed by state licensing boards and by ethics boards of professional mental health associations involve this type of alleged misconduct. In a national survey of psychologists (Pope & Vetter, 1991), half the respondents reported assessing or treating at least one client who had been sexually intimate with a prior therapist, a total of 958 separate instances; 90 percent of these encounters were judged to have been of harm to the client, with an 11 percent subsequent hospitalization rate and a 14 percent rate of attempted suicide. Most of the victims (87 percent) were female, and three of them were children.

Even these chilling statistics, however, do not do justice to the magnitude of the problem in terms of already vulnerable lives being further undermined, nor do they speak to the difficulties victims often have in seeking redress for their psychic injury. That gap has been partially filled with the publication of a remarkable and courageous book by Bates and Brodsky (1989) that deals informatively with these subjects. In it, Bates renders a compelling account of her own sexual victimization by a therapist, one who, incredibly, has given a prominent address on "the problem" before a national professional audience. Her "second victimization," involving painful and humiliating experiences, occurred when she instituted legal means to discourage this man from further violations of professional trust. The book, thoroughly researched, offers little encouragement that an offender in this area can be reliably rehabilitated, and yet it has proven extremely difficult to achieve prevention through license revocation or other professional or legal sanction.

Even allowing for the likelihood of occasional fraudulent or frivolous client complaints in this area—the Pope and Vetter data suggest a frequency of 4 percent—the well-established occurrence of this type of event indicates an appalling level of misconduct, and probable client injury, among people holding themselves out to be "psychotherapists," which incidentally is not in most jurisdictions a legally regulated self-description. A prospective client seeking therapy needs to be sufficiently wary to determine that the therapist chosen is one of the large majority committed to high ethical and professional standards.

Unfortunately, there are otherwise few guidelines a prospective client can reliably employ in choosing a therapist. Reputation in the community and among professional colleagues and quality of background training and experience are obvious things to consider. We think that a "trial" interview or brief series of them is a good idea as a means of assessing one's "fit" and comfort with a given therapist's style. In the end, however, we do not have the data to predict with even reasonable assurance the outcome or likely benefit of any particular therapist-client relationship. This is a knowledge gap on which research is badly needed.

Finally, we should comment briefly on the seeming disarray of the field of therapy with its many competing variations. One aspect of the competition, already noted, involves a currently intense struggle, fueled by interprofessional rivalries, concerning the place of biological therapies in the mental health field. In this chapter we focus on the several varieties of psychosocial approach. We have already indicated our judgment that probably most of these are "right," at least in the limited sense that they have fashioned intervention techniques having a high probability, when sensitively applied, of helping people overcome their problems. The obvious question, then, is this: Why doesn't the typical therapist employ a multifaceted, multitargeted approach to every client with whom treatment is undertaken, instead of doing his or her "own thing," be it psychoanalysis, behavioral, gestalt, or some other therapy? Wouldn't this approach maximize treatment efficiency? We suspect so, and we have no entirely satisfactory answer to the first part of our query. Ideological commitment has historically been very strong in this field—in large part because virtually nobody had solid research data with which to back their claims. That situation is changing rapidly, but the commitment tends to remain despite the change and despite sincere efforts (e.g., Goldfried et al., 1990; Goldfried & Safran, 1986; Norcross & Goldfried, 1992) to enhance communication across the many intersecting barriers. As every therapist knows, dysfunctional habits are often hard to break.

## SUMMARY

Psychotherapy is aimed at the reduction of abnormal behavior in individuals through psychological means. The goals of psychotherapy include changing maladaptive behavior, minimizing or eliminating stressful environmental conditions, reducing negative affect, improving interpersonal competencies, resolving personal conflicts, modifying a person's inaccurate assumptions about himself or herself, and fostering a more positive self-image. Although these goals are by no means easy to achieve, psychological treatment methods have been shown to be generally effective in promoting adaptive psychological functioning in many troubled people.

Many approaches to psychological treatment ("schools of psychotherapy") have been developed to treat individuals with psychological disorders. We have organized these approaches into a scheme that focuses attention on the primary target selected for intervention, employing the acronym CAPER. Type C therapies are directed at a client's maladaptive Cognitions; Type A at dysregulated Affects or emotions; Type P at pathogenic Physiologic reactions or states; Type E at the reactive Environment; and Type R at the aberrant behavioral Responses themselves. We argued that, because these elements are organized in an unending loop, positive change in any one of them will produce a good therapeutic effect overall.

Nevertheless, this chapter is developed in accord with the traditional breakdown of "schools" of therapy. One of the oldest approaches to psychological treatment, psychoanalysis, was originated nearly a century ago by Sigmund Freud. Although complicated systems of psychodynamic therapy have evolved since Freud's time, many features of "orthodox" psychoanalysis today closely resemble Freud's original system. Several other schools of therapy have developed out of the psychoanalytic tradition. These approaches accept some elements of Freudian theory but diverge on key points, such as the length of time to be devoted to therapy or the role of the ego in personality dynamics. By and large, we consider them Type E therapies because of the attention they give to the management of "transference."

A second major approach to psychological intervention is behavior therapy. Originating over 50 years ago, behavior therapy has come to be used extensively in treating clinical problems. Behavior therapy approaches make use of a number of techniques, such as systematic desensitization and biofeedback (which are Type A and Type P therapies, respectively). Other behavior therapy techniques include aversion therapy, modeling, reinforcement approaches, and assertiveness therapy (all Type R therapies). Recently, behavior therapy methods have been applied to internal processes—that is, thought or cognitions (Type C)—with a great deal of success. Known as cognitive-behavioral therapy, this approach attempts to modify a person's self-statements to change his or her behavior. Cognitive-behavioral methods have been used for a wide variety of clinical problems—from depression to anger control—and with a range of clinical populations.

Several other psychological treatment methods have been referred to as humanistic-experiential therapies (which we regard as primarily Type C, owing to their focus on "awareness"). One of the earliest of these approaches is the client-centered, or person-centered, therapy of Carl Rogers. This treatment approach, originating in the 1940s, has received broad acceptance and has provided a valuable conceptualization of the client-therapist interaction as well as specific techniques for generating personal change or personal growth in motivated clients.

In addition to individual treatment approaches, some psychological treatment methods are applied in group settings, such as group therapy and marital or family therapy. These approaches typically assume that a person's problems lie partly in his or her interactions with others. Consequently, the focus of treatment is to change ways of interacting among individuals in the social or family context (a Type E approach).

In recent years an attempt has been made to integrate behavior therapy methods with other psychological treatment approaches, particularly psychodynamic therapy. This effort is a result of the recognition that elements from both approaches can be used to increase our understanding of troubled clients and to bring about desired behavior changes. These integration issues are actually part of a broader problem of therapists largely doing their "own thing," addressed in the chapter's "Unresolved Issues" section.

Evaluation of the success of psychotherapy in producing desired changes in clients is difficult. Research in psychotherapy, however, has shown that most treatment approaches are more effective than no treatment at all. Beyond the question of evaluating the success of psychotherapy lie other, larger questions involving the ethical dilemmas posed by therapy. Does psychotherapy encourage conformity to the status quo? Should it do this? These constitute some of the difficult moral and social issues that daily confront mental health professionals.

Other unresolved issues include the often perplexing occurrence of negative or deteriorative outcomes in psychotherapy. One likely source of such outcomes, by no means the only or necessarily most common, is sexual misconduct on the part of a therapist.

SUMMARY
KEY TERMS

Over the years, most efforts toward mental health have been largely restorative, geared toward helping people only after they have already developed serious problems. Before the 1960s, mental health professionals typically did not become involved until after an individual had suffered a breakdown; then they often sent such persons for treatment far away from their home communities, often compounding their distress and disrupting their lives.

Seemingly, a more effective strategy would be to try to catch problems before they become severe, or better yet, to establish conditions in which psychological disorders will not occur. The causes of many mental disorders, however, are not sufficiently understood to enable practitioners to initiate explicit preventive programs. Efforts toward prevention in the mental health field are still based largely on hypotheses about what works rather than on substantial empirical research. Nonetheless, many professionals believe that preventive mental health efforts are worthwhile.

Of course, preventive efforts, like treatment programs, cost money. During periods of economic decline, federal, state, and local governments typically reduce their support for such programs. Unfortunately, programs aimed at prevention, because of their long-range scope and their often indirect focus, are considered to be relatively unattractive because they appear less cost-effective than other programs with more obvious outcome criteria. The irony, of course, is that prevention can be in the long run far less costly than the treatment of mental disorders and their effects (Lorion, 1990).

Where preventive efforts fail and a serious mental health problem develops, today's professionals emphasize the importance of prompt treatment. It is considered preferable, too, that the treatment be in the individual's own community so that clinicians can use available family and other familiar supports and minimize the disruption to the person's life. If hospitalization becomes necessary, every effort is made to prevent the disorder from becoming chronic and to return the person to the community as soon as possible, with whatever aftercare and continued support may be needed. On occasion, as is obvious to even the casual urban observer, such efforts fail, and a person is sent back into the community without adequate support and well before he or she is capable of independent functioning.

In this last chapter, we will examine the kinds of measures that are being taken to prevent maladaptive behavior or limit its seriousness. Our discussion will begin with a review of preventive strategies.

Next, we will explore some factors related to the care and hospitalization of people with severe psychological problems: commitment, deinstitutionalization, and assessment of dangerousness. Closely related to these factors are the matters of (a) a therapist's duty to warn others if a client threatens violence and (b) the use—and some think abuse—of the insanity defense as a plea in capital crimes. Next, we will briefly survey the scope of organized efforts for mental health both in the United States and throughout the world. Finally, we will conclude the chapter by considering what each of us can do to foster mental health.

# PERSPECTIVES ON PREVENTION

In our present discussion we will use the concepts of primary, secondary, and tertiary prevention, which are widely used in public health efforts to describe general strategies of disease prevention. **Primary prevention** is aimed at reducing the possibility of disease or disorder and fostering positive health. **Secondary prevention** is typically emergency or crisis intervention, and involves efforts to reduce the impact, duration, or spread of a problem that has already developed—if possible, catching it before it has become serious. **Tertiary prevention** seeks to reduce the long-term consequences of disorders or serious problems. These preventive strategies, although primarily devised for understanding and controlling infectious physical diseases, provide a useful perspective in the mental health field as well. As we hope to show, all three types of intervention are of critical importance in reducing the enormous toll of mentally disordered functioning in our society.

## Primary Prevention

We begin our discussion of primary prevention with the recently published report of a panel of experts in the field appointed to advise a conference on prevention sponsored by the National Institute of Mental Health (Coie et al., 1993). The panel identified as a recognizable area of inquiry the field of "prevention science," outlined a conceptual framework defining the boundaries of this discipline, and recommended certain directions for a proposed national research program that would capitalize on the knowledge already amassed by investigators working in this and closely related areas. They focused their discussion on those influences considered to be likely or potential "precursors of dysfunction or health, called *risk factors* and *protective factors,* respectively" (p. 1013).

The panel summarized its findings in a set of basic observations, which may be paraphrased as follows:

1. *Risk factors have complex relations to clinical disorders.* That is, it is rare for either particular risk factors or particular disorders to be related to one another in specific and exclusive ways. Rather, particular disorders (e.g., schizophrenia) are usually found to be associated not with single risk factors but with a host of differing ones; similarly, particular risk factors (e.g., physical abuse) are only rarely found to have a range of effect limited to only one or a very few types of disorder, presumably because they tend to disrupt adaptive developmental processes in many different ways at different developmental stages. Also, personal characteristics may interact with environmental risk factors in ways that may enhance or mitigate their pathogenic effects.

2. *The salience of risk factors may fluctuate developmentally.* In other words, certain risk factors are associated with deleterious effects only if they occur during a limited span of the developmental years, while others seem to operate over a much longer developmental span. For example, association with deviant peers may be predictive of antisocial behavior only in adolescence, whereas parental neglect appears to be a risk factor from childhood through adolescence.

3. *Exposure to many risk factors has cumulative effects.* That is, multiple risk factors have additive effects with respect to a person's overall vulnerability to mental disorder. The probability of a disordered outcome increases with increases in the number, duration, and potency ("toxicity") of the risk factors to which the person has been exposed.

4. *Diverse disorders share fundamental risk factors in common.* There appear to be certain "generic" risk factors whose effects are very widespread in terms of the variety of pathologic outcomes with which they are associated. The panel provided a list of 30 such factors, assorted into various categories and reproduced in Table 18.1, that are known to be associated with many types of adult disorder.

5. *Promoting protective factors against dysfunction.* As was noted in Chapter 3, risk exposure, even at extreme levels, does not invariably predict disorder. The effects of risk factors can be reduced by a variety of protective elements either within the person or the surrounding social environment. For ex-

**Table 18.1** *Risk Factors Known to be Associated with Psychological Disorder*

- **Family Circumstances**
  - Low social class
  - Family conflict
  - Mental illness in the family
  - Large family size
  - Poor bonding to parents
  - Family disorganization
  - Communication deviance
- **Emotional Difficulties**
  - Child abuse
  - Apathy or emotional blunting
  - Emotional immaturity
  - Stressful life events
  - Low self-esteem
  - Emotional dyscontrol
- **School Problems**
  - Academic failure
  - Scholastic demoralization
- **Ecological Context**
  - Neighborhood disorganization
  - Racial injustice
  - Unemployment
  - Extreme poverty
- **Constitutional Handicaps**
  - Perinatal complications
  - Sensory disabilities
  - Organic handicaps
  - Neurochemical imbalance
- **Interpersonal Problems**
  - Peer rejection
  - Alienation and isolation
- **Skill Development Delays**
  - Subnormal intelligence
  - Social incompetence
  - Attentional deficits
  - Reading disabilities
  - Poor work skills and habits

(Coie et al., 1993, p. 1022)

ample, the occurrence of childhood disorders appears to be mitigated by certain individual characteristics pertaining to temperament, personality dispositions, and skills, and also by a protective environment that provides parental warmth, social support, appropriate monitoring and supervision, and opportunity for bonding with prosocial models. Where risk factors are difficult to identify or to eliminate, the most effective preventive strategy may involve attempts to enhance protective factors.

In short, we are concerned in primary prevention with two key tasks: altering conditions that can cause or contribute to mental disorders (risk factors) and establishing conditions that foster positive mental health (protective factors). Epidemiological studies are particularly important in this area because they help investigators obtain information about the incidence and distribution of various maladaptive behaviors needing prevention efforts (Dohrenwend & Dohrenwend, 1982). These findings can then be used to suggest what preventive efforts might be most appropriate. For example, various epidemiological studies and reviews have shown that certain groups are at high risk for mental disorders, including recently divorced people (Bloom et al., 1978), the physically disabled (Freemen, Malkin, & Hastings, 1975), elderly people living alone (Neugarten, 1977), physically abused children (Malinosky-Rummel & Hansen, 1993), and people who have been uprooted from their homes (Westermeyer et al., 1991). Although findings such as these may be the basis for immediate secondary prevention, they may also aid later in primary prevention by telling us what to look for and where to look—in essence by focusing our efforts in the right direction. Primary prevention includes biological, psychosocial, and sociocultural efforts. As Kessler and Albee (1975) have noted, "Everything aimed at improving the human condition, at making life more fulfilling and meaningful, may be considered to be part of primary prevention of mental or emotional disturbance" (p. 557).

**Biological Measures** Biologically based primary prevention begins with help in family planning and includes both prenatal and postnatal care. A good deal of current emphasis is being placed on guidance in family planning—how many children to have, when to have them in relation to marital and other family conditions, and even whether to have children at all. Such guidance may include genetic counseling, in which tests for genetic defects may be given to potential parents to assess their risk of having children with birth defects that can result in mental disorders.

Breakthroughs in genetic research have also made it possible to detect and sometimes alleviate genetic defects before a baby is born; when in utero treatment is not feasible, such information provides the parents with the choice of having an abortion rather than going on to bear a baby with serious defects. Continued progress in genetic research may make it possible to identify genetic disorders early or even to correct faulty genes, thus providing humankind with fantastic new power to prevent hereditary pathology.

Many of the goals of health psychology can also be viewed as primary prevention. Efforts geared toward improving one's diet, establishing a routine of physical exercise, and developing overall good health habits can do much to improve one's physical well-being. To the extent that physical illness always produces some sort of psychological stress that can result in such problems as depression, good health is primary prevention with respect to good mental health.

**Psychosocial Measures** In regarding normality as optimal development and functioning rather than as the mere absence of pathology, we imply that people need opportunities to learn physical, intellectual, emotional, and social competencies. The first requirement of psychosocial "health" is that a person develop the skills needed for effective problem solving, for expressing emotions constructively, and for satisfying relationships with others; failure to develop these "protective" skills places the individual at a serious disadvantage in coping with stresses and often unavoidable mental disorder risk factors.

The second requirement for psychosocial health is that a person acquire an accurate frame of reference on which to build his or her identity. We have seen repeatedly that when people's assumptions about themselves or their world are inaccurate, their behavior is likely to be maladaptive. Likewise, an inability to find satisfying values that foster a meaningful and fulfilling life constitutes a fertile source of maladjustment and mental disorders.

Third, psychosocial well-being also requires preparation for the types of problems a person is likely to encounter during given life stages. For example, pregnancy and childbirth usually have a great deal of emotional significance for both parents; in addition, the arrival of a new infant in the home places an enormously increased demand on the resources of caregivers and may disturb family equilibrium or exacerbate an already disturbed marital situation. Young people who want to marry and have children must be prepared for the tasks of building a mutually satisfying relationship and helping children develop their abilities. The latter is a particularly formidable responsibility for teenage parents, who are themselves still struggling to become independent adults. Similarly, a person needs to be prepared adequately for other developmental tasks characteristic of given life periods, including retirement and old age.

In recent years, psychosocial measures aimed at primary prevention have received a great deal of attention. The field of behavioral medicine has had substantial influence here. As we saw in Chapter 8, efforts are being made to change the psychological factors underlying unhealthful habits, such as smoking, excessive drinking, and poor eating, that may be contributing to the development of both physical and psychological problems.

**Sociocultural Measures** The relationship between an individual and his or her community is a reciprocal one, a fact Americans sometimes forget in a culture that has historically placed an unusually high value on individualism. We need autonomy and freedom to be ourselves, but we also need to belong

*Parenting education is one of several early-intervention, primary prevention strategies.*

and contribute to a community. Without a supportive community, individual development is stifled.

At the same time, without responsible, psychologically healthy individuals, the community will not thrive and, in turn, cannot be supportive. When a community begins to fail, therefore, there is considerable danger that the failure will become self-sustaining; the psychosocially impaired victims of disorganized communities lack the wherewithal to create better communities to protect and sustain the psychological health of those who come after them, thus ensuring a persistently unprotective environment. Sociocultural efforts toward primary prevention are focused on making the community as nourishing as possible for the individuals within it.

With our growing realization of the importance of pathological social conditions in producing maladaptive behavior, increased attention must be devoted to creating social conditions that will foster healthy development and functioning in individuals. Efforts to create these conditions are seen in a broad spectrum of social measures ranging from public education and Social Security to economic planning and social legislation directed at ensuring adequate health care for all citizens.

Primary prevention through social change in the community is difficult. Although the whole psychological climate can ultimately be changed by a social movement, such as the civil rights movement of the 1960s, the payoff of such efforts is generally far in the future and may be difficult or impossible to predict or measure. Efforts at psychologically desirable social change are also likely to involve ideological and political issues that may inspire powerful opposition, including opposition from government itself. According to an analysis by Humphreys and Rappaport (1993), for example, the Reagan and Bush administrations during the 1980s severely undercut Community Mental Health Center social programs in favor of agencies involved in the "war on drugs." This effort, in redirecting attention to purported defects of individual character, was said to be more in keeping with a conservative political philosophy; that is, the basic problem, according to this view, is one of personal moral weakness ("How should kids deal with a drug-saturated environment? Just say no."), *not* social disorganization. Although drug abuse *is* a matter of individual behavior, it does not follow that countermeasures must be individually directed. Some examples of more broad-based programs are given in what follows.

### An Illustration of Primary Prevention Strategies

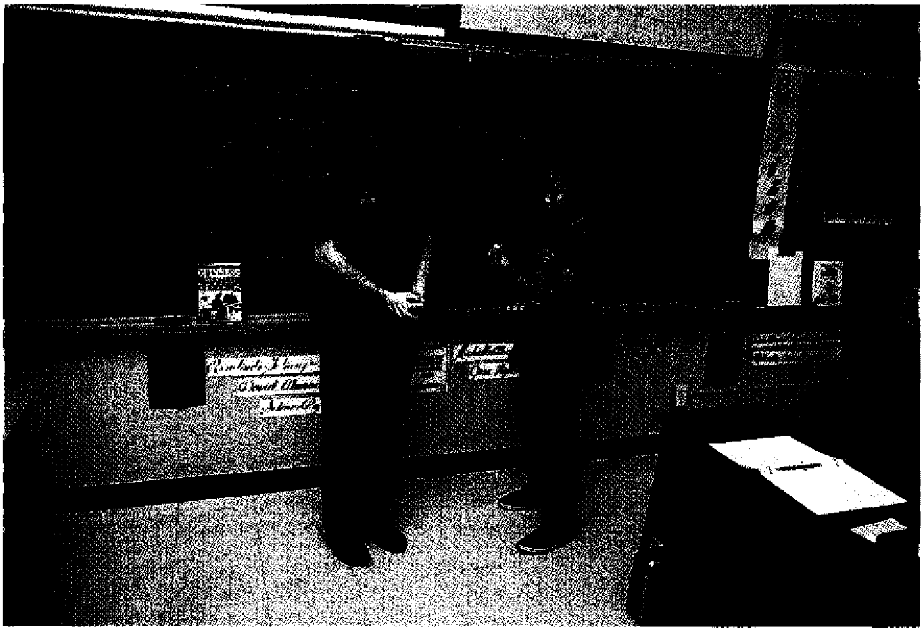
Though difficult to formulate and even more difficult to mobilize and carry out, primary prevention efforts can bring about major improvements if successful. We will look in this section at the mobilization of primary prevention resources aimed at curtailing or reducing the problem of teenage alcohol and drug abuse.

Although drug use among most adolescent groups has declined in recent times (Oetting & Beauvais, 1990), teenage drug and alcohol use is still viewed as one of today's most significant psychological and community problems. Mental health professionals and political figures alike have called for a more concerted effort to deal with this enormous social problem. It is clear that traditional health or psychological intervention models, aimed at individual remediation only after a youngster has become addicted to narcotics or alcohol, have not significantly reduced the problem of drug and alcohol abuse among teenagers. Moreover, these treatment approaches are typically implemented only after the child has seriously compromised his or her life opportunities through drug or alcohol use.

Many contemporary researchers and theorists have taken a more proactive position. They have attempted to establish programs that prevent the development of abuse disorders before young people become so involved with drugs or alcohol that their lives are altered to the point that future adjustment becomes difficult, if not impossible. These recent prevention strategies have taken several diverse and hopeful directions, addressing somewhat different aspects of teenagers' lives. We will examine several that show promise and then discuss the limitations of these prevention approaches.

*Education Programs.* Drug and alcohol education programs represent a prevention strategy aimed at providing information about the damaging effects of these substances. Many are school-based and are usually premised on the idea that if children are made aware of the dangers of drugs and alcohol, they will choose not to begin using them. Englander-Golden and colleagues (1986), for example, provided "Say it straight" training to sixth through eighth graders in which they taught them both the dangers of drug and alcohol abuse and how to be assertive enough to resist drugs and alcohol in spite of peer pressure. In a follow-up evaluation, these investigators reported that youngsters who were trained in the program had a lower rate of drug- and alcohol-related suspensions from school than did children who received no training.

A similar program, Project Northland, geared to the prevention of alcohol abuse, targets junior high school students in northeastern Minnesota, but involves a much broader community-wide intervention effort (Perry et al., 1993). One of its facets, for



*Efforts to teach school children about the dangers of drugs before they reach the age of maximum risk have become common.*

example, is home-based and recruits parents to participate with their children in exercises designed to enhance awareness of the risks of alcohol abuse; preliminary findings are encouraging (Williams et al., in press).

*Intervention Programs for High-Risk Teens.* Intervention programs involve identifying high-risk teenagers and providing special approaches to circumvent their further use of alcohol or potentially dangerous drugs. Programs such as these are often school-based efforts and are not strictly prevention programs; rather, they are treatment programs that provide early intervention for high-risk teens who are vulnerable to drug or alcohol use, in order to reduce the likelihood of their becoming further involved with these substances. Newman and colleagues (1988–1989) described a procedure for the early identification of young people who are having difficulties in school because of drug and alcohol use. The developers of this program train teachers and administrators to identify and manage alcohol- and drug-use problems. Critical to this intervention is a fair and consistently enforced drug and alcohol policy in the schools.

*Parent Education and Family-Based Intervention Programs.* Because parents typically underestimate their own children's drug and alcohol use (Silverman & Silverman, 1987), several programs have been aimed at increasing parents' awareness of the extent of the problem and at teaching them ways to deal with drug and alcohol use in the family context. These programs teach parents how to recognize drug- or alcohol-abuse problems so that youngsters can be diverted away from negative and self-destructive behaviors. One such program by Grady, Gersick, and Boratynski (1985) worked with parents whose children were about to become teenagers. They first assessed parents' skill in dealing with drug-related issues; then they trained parents to understand and respond empathically to youngsters who might be exposed to drugs during their adolescent years. Parents were then taught to respond to their children's questions and concerns and to help them consider alternative, more adaptive behavior.

Other family-oriented programs have aimed at strengthening family bonds and providing more positive family relationships to insulate a child from external negative influences. For example, DeMarsh and Kumpfer (1985) developed a program that focused on involving parents or a family in the positive socialization of a child by increasing communications within the family and enhancing parents' child-management skills.

When there is a drug or alcohol problem, assuring family cooperation in the treatment program can be problematic, and many programs have reported low rates of participation. In an effort to increase the participation rate, Szapocznik and colleagues (1988) used family-systems therapeutic techniques to reduce the resistance of families to drug treatment. They reported that 77 percent of the families completed the treatment program compared with only 25 percent in a control condition.

*Peer Group Influence Programs.* Clearly, peers exert a powerful influence on teenagers in every aspect of their lives, including drug and alcohol abuse. Programs designed to help youngsters overcome negative pressures from peers focus on teaching social skills and assertiveness. Of course, peer pressure can be positive as well—in this case, influencing a teen not to use drugs or alcohol—and many programs focus on the positive aspects of peer pressure. Swadi and Zeitlin (1988) advocated the positive use of peer influence because for teenagers such influence seems much more powerful than the influence of others, including teachers and parents.

*Programs to Increase Self-Esteem.* Programs designed to increase a sense of self-worth attempt to ensure that young people will be able to fend for themselves more assuredly and not fall into dependent, negative relationships with stronger and more dominant peers. Pentz (1983) designed one such program by providing teenagers with social-skills training and the modeling of appropriate behaviors to reduce drug use and other related negative behaviors, such as truancy. In another program, Botvin (1983) relied on cognitive-behavioral intervention techniques to enhance teenagers' feelings of competency in basic life skills and improve their problem-solving skills. This approach was thought to be effective in reducing the impact of tobacco, alcohol, and marijuana use (Botvin et al., 1990).

*Mass Media and Modeling Programs.* Recognizing the huge "market" potential of teenagers, advertisers have been adept in exploiting the tremendous value the appearance of sophistication has for this age group. Most youngsters are bombarded with drug- or alcohol-related stimuli in TV commercials, movies, and other visual blitzes. Airing such TV commercials or programs at times that children may view them serves to glamorize alcohol or drug use. Several recent efforts have been aimed at deglamorizing or counteracting these messages by showing commercials that graphically depict the negative aspects of alcohol and drug use (Coombs, Paulson, & Palley, 1988; Schilling & McAlister, 1990).

The various prevention strategies discussed here are by no means mutually exclusive. Most programs do not rely on a single intervention strategy but incorporate two or more (Forman & Linney, 1988; Perry & Murray, 1985). For example, Botvin and Tortu (1988) described a five-stage program involving both didactic and peer interaction interventions designed to enhance youngsters' self-esteem and enable them to function effectively in social contexts to resist negative peer influences. In the first component of this program, several sessions are devoted to biofeedback demonstrations of the effects of cigarettes, marijuana, and alcohol on heart rate. In the second component, several sessions are aimed at teaching participants how to make effective decisions. In the third component, sessions focus on aiding the youngsters in understanding their self-image and improving their self-esteem. In the fourth component, teenagers are taught to deal with anxiety, particularly social anxiety. Finally, the fifth component of the program involves training the teens in both social communication and assertiveness, thus ensuring a more effective peer group interaction.

How successful are primary prevention programs at reducing the overall impact of adolescent drug and alcohol use? It is difficult to say. Some researchers have concluded that drug and alcohol education programs have only limited success (Tobler, 1986). Conducting rigorous research in primary prevention is often problematic because the interventions may be only remotely connected to the behavior being targeted for change. Moreover, it is typically impossible to monitor and control in a single study all of the relevant variables influencing drug and alcohol use. Clearly, too, it is difficult to provide a powerful enough intervention to offset the motivation to use or sell drugs many youngsters experience. For many young people living in extreme poverty, the only way they can tolerate or possibly get out of the ghetto is through using or selling drugs. The recent decline in drug use among teenagers does not include minorities living in ghettos, barrios, or American Indian reservations, where drug use continues to grow at record levels (Oetting & Beauvais, 1990).

Some critics of drug and alcohol prevention programs consider drug and alcohol problems in adolescence to be the result of early socialization processes—and not amenable to superficial reeducation efforts occurring so late in a youngster's life. Shedler and Block (1990), in a well-controlled longitudinal study in which subjects were carefully studied from about age 5 to age 18, found clear precursors to frequent drug use in the youngsters' early personality development. They found that teenagers developing drug-abuse patterns in their late teens had clear psychological maladjustment in early childhood, well before they were exposed to drugs; these psychological problems predisposed the adolescents to drug abuse. As such, Shedler and Block considered the "peer-centered" or recent environmental influence explanations to be flawed and inadequate to explain the behavior. They thus argued that many of the drug education program efforts are inadequate to address the true source of the problem: the personality syndrome that appears to underlie drug abuse.

We must be careful in assessing this conclusion, however, in part because it might be viewed as implying that intervention efforts are doomed to failure in the face of behavioral propensities that are predetermined and unalterable, thus justifying public inaction and an attitude of helplessness. Few investigators have ever doubted that relatively enduring personality risk factors make certain children more vulnerable than their less-troubled peers to the attractions of drug and alcohol abuse. On the other side of the coin is the example of some unusually resourceful youngsters who have emerged drug-free from deplorably high-risk environments. The point is that acknowledging the significant contribution early-appearing personal dispositions may make to outcomes does not imply that attempts to modify negative environmental influences are irrelevant. It would appear that we need to intensify efforts at early identification of those children whose personality development is veering toward a high-risk status and to apply intervention techniques to divert this trend.

Unfortunately, many of the recent programs that have been initiated in response to the drug crisis are of the "too little, too late" variety. The lackluster performance or outright failure of some drug prevention efforts may hinder future research. Because of the lack of clear research findings and the uncertain effectiveness of prevention programs, it is difficult to convince lawmakers or funding agencies that more support for such programs is needed or worth the effort. Policy makers may take such unproductive results as an indication that primary prevention efforts are not effective in reducing the problem behavior being addressed. Thus more substantial, better-designed, and longer-range programs that might be powerful enough to bring about major changes may not be supported.

## Secondary Prevention

Secondary prevention emphasizes the early detection and prompt treatment of maladaptive behavior in a person's family and community setting. In some cases—for example, in a crisis or after a disaster—secondary prevention involves immediate and relatively brief intervention to prevent any long-term behavioral consequences. In other cases, secondary prevention is aimed at longer-term consulting and educational services to reduce the consequences of some identified maladaptive behavior or problem. We will look briefly at both types of secondary prevention and then follow with an in-depth examination of secondary prevention efforts after an airplane crash.

**Crisis Intervention** Crisis intervention has emerged in response to a widespread need for immediate help for individuals and families confronted with especially stressful situations—be they disasters or family situations that have become intolerable (Auerbach & Stolberg, 1986; Butcher & Dunn, 1989; Butcher, Stelmachers, & Maudal, 1983; Gist & Lubin, 1989; Mitchell & Resnik, 1981; Taylor, 1989). Often, people in crisis are in a state of acute turmoil and feel overwhelmed and incapable of dealing with the stress by themselves. They do not have time to wait for the customary initial therapy appointment, nor are they usually in a position to continue therapy over a sustained period of time. They need immediate assistance.

To meet this need, two modes of therapeutic intervention have been developed: (a) short-term crisis therapy involving face-to-face discussion; and (b) the telephone hot line. These forms of crisis intervention are usually handled either by professional mental health personnel or by paraprofessionals—lay people who have been trained for this work.

*Short-Term Crisis Therapy.* **Short-term crisis therapy,** as the name implies, is of brief duration and focuses on the immediate problem with which an individual or family is having difficulty. Although medical problems may also require emergency treatment, we are concerned here with personal or family problems of an emotional nature. In such crisis situations, a therapist is usually very active, helping to clarify the problem, suggesting plans of action, providing reassurance, and otherwise giving needed information and support. In essence, the therapist tries to provide as much help as the individual or family will accept.

If the problem involves psychological disturbance in one of the family members, emphasis is usually placed on mobilizing the support of other family members. Often this enables the person to avoid hospitalization and a disruption of family life. Crisis intervention may also involve bringing other mental health or medical personnel into the treatment picture. Most individuals and families who come for short-term crisis therapy do not continue in treatment for more than one to six sessions. An example of crisis intervention as a secondary preventive effort is given in HIGHLIGHT 18.1.

*The Telephone Hot Line.* As we noted in Chapter 6, recent years have seen a new approach to dealing with people undergoing crises—the telephone hot line. Today all major cities in the United States and most smaller ones have developed some form of telephone hot line to help people undergoing peri-

18.1

## Crisis Intervention in Troubled Families

Family crises can result from many sources; for example, a family may lose its home through economic emergency, or a family member may die or become severely ill, or one of the family members may become psychotic, or, as in the following case, one of the family members may attempt suicide:

> A 17-year-old girl, Leah, was brought into the emergency department of a general hospital by her mother, father, and maternal grandmother. She had walked into her parents' bedroom earlier in the morning and announced that she had swallowed all her mother's pills. The parents had brought their daughter for emergency medical treatment and were enraged when a psychiatrist was called. The history was obtained from mother, since Leah said little, and mother answered every question. During the interview, father paced in and out of the room, repeatedly declaring that he was taking his daughter home. He aggressively asked each person who entered the room "What do you want?" but each time left before a response was possible. Grandmother sat in the room, announcing from time to time, "That girl always makes trouble."
>
> Leah was the oldest of three children. None of them attended school. According to mother, she tutored them at home. Mother also worked outside of the home and complained about how much she had to do. Leah "won't even go to the store alone, so I must accompany her everywhere." Mother said that her husband had told her not to bother with Leah, who would only get married and leave them anyway. But she (mother) had to "bother" because Leah could not go out alone in their neighborhood.
>
> When asked about the suicide attempt, Leah said she would "do it again" if she went home. She wanted to talk to someone about the fights with mother that made her so angry she wanted to die. Mother said it was father's fault. He worked erratically, drank heavily, and made them live in a bad house in a poor neighborhood. They had terrible neighbors who were "nosey" and bothered them.
>
> Since Leah had indicated she still had suicidal intentions and the family conflict continued unabated, hospitalization was recommended. In response, Leah immediately announced she was better and would go home. She said she would not stay in the hospital. Her mother said she could never persuade her to stay and the family gathered itself up to leave (Kress, 1984, p. 419-420).

The family crisis in this case brought to light several difficult problems due, in part, to the psychopathology of the individuals in the family—adjustment problems that threatened the integrity of the family organization. While Leah appeared to be the most disturbed, other family members seemed to have significant psychological problems that directly affected the family strife as well. The suicide attempt, like many other crises a family is unprepared to resolve, required outside intervention. Not only was an immediate solution needed for the present emergency, but psychological intervention for the longer-term problem of the family's inability to resolve conflict was recommended. However, the closed, almost reclusive, nature of the family suggested that treatment for the individuals involved and for the disturbed family relationships, though needed, was not likely to be accepted at that point. Neither Leah nor her father appeared open to examining their problems or to changing their behavior. Unfortunately, we have no follow-up on the case of Leah. This is often the situation in crisis therapy, where the intervention efforts are limited to what can be accomplished only during the immediate crisis; that is, many such clients never return for more therapy, no matter how adamant the crisis worker's recommendation that they do so.

As is by now obvious, crisis intervention therapy with families is usually different and more limited in scope than family therapy as described in Chapter 17. The goals of family crisis intervention do not involve changing the basic family functioning, as in family therapy, but are usually limited to returning a disrupted family to precrisis functioning (Umana, Gross, & McConville, 1980). For example, the mental health practitioner's task in the case of Leah involved resolving the immediate emergency and helping ease her life-threatening state of mind while, hopefully, engaging her family in future family or individual treatment to resolve the pressing problems that appeared to have caused the immediate crisis, but this didn't happen.

ods of severe stress. Although the threat of suicide is the most dramatic example, the range of problems that people call about is virtually unlimited—from breaking up with someone to being on a bad drug trip. In addition, there are specific hot lines in various communities for rape victims and for runaways who need assistance.

As with other crisis intervention, a person handling hot-line calls is confronted with the problem of rapidly assessing what is wrong and how bad it is. Even if an accurate assessment is possible and the hot-line worker does everything within his or her power to help the caller, a distraught person may hang up without leaving any name, telephone number, or address. This can be a deeply disturbing experience for the hot-line counselor—particularly if, for example, the caller has announced that he or she has just swallowed a lethal dose of sleeping pills. Even in less severe cases, of course, the hot-line worker may never learn whether the caller's problem has been solved. In other instances, however, the caller may be induced to come in for counseling, making more personal contact possible.

For a therapist or volunteer counselor, crisis intervention is probably the most discouraging of any treatment approach that we have discussed. The urgency of the intervention and the frequent inability to provide any therapeutic closure or follow-up are probably key factors in this discouragement. Free clinics and crisis centers have reported that their counselors—many of whom are volunteers—tend to burn out after a short period of time. Despite the high frustration level of this work, however, crisis intervention counselors fill a crucial need in the mental health field, particularly for the young people who make up most of their clients. This need is recognized by the many community mental health centers and general hospitals that provide emergency psychological services, either through hot lines or walk-in services. For thousands of people in desperate trouble, an invaluable social support is provided by the fact that there is somewhere they can go for immediate help or someone they can call who will listen to their problems and try to help them. Thus the continuing need for crisis intervention services and telephone hot lines is evident.

**Consultation and Education of Intermediaries** Often, community mental health professionals, such as psychologists and psychiatrists, are able to reach a larger group of people in need of secondary prevention efforts by working through primary care professionals, such as teachers, social workers, and police personnel (Iscoe, Bloom, & Spielberger, 1977; Levine & Perkins, 1987; Mann, 1978). For such programs, mental health professionals identify a population at risk for the development of psychological disorder and then work with the personnel in community institutions who have frequent contact with members of this population. For example, police officers might be trained to direct persons involved in domestic quarrels to seek mental health services rather than to settle their differences through violence.

Mental health professionals had originally intended that *consultation and education* (C & E) be included among the services offered by all community mental health centers. According to this plan, the impact of these centers, while more indirect, could be much more widely distributed—helping people experiencing problems by increasing the skill and sensitivity of those who routinely come into contact with them in the community and are in a position to make their lives either more stressful or less so. Currently, however, most community mental health centers provide little such indirect care, having become deluged with the problems of providing direct service, including dispensing and monitoring the effects of psychoactive drugs, to overwhelming numbers of mental hospital patients discharged into the community by deinstitutionalization. Many centers have managed to maintain a C & E relationship with schools or other juvenile services, but for the most part the widespread outreach function originally envisaged for community mental health centers has been abandoned, very often because of a low priority in funding. Thus has another good idea in prevention come essentially to naught in encounters with governmental bureaucracies preoccupied with the achievement of immediate and highly visible results.

**An Illustration of Secondary Prevention** The immediate consequences of an air crash are devastating. Survivors typically have traumatic responses to the accident that impair their immediate functioning and place great demands on their psychological adjustment for weeks after the disaster. Family members of victims often experience extensive psychological trauma after the accident; they may need to make extensive changes during their loved one's lengthy recovery period or, more likely, they will need to make major life changes to adjust to their loved one's death. Even rescue personnel caught up in dealing with the aftermath of an airline disaster may suffer from posttraumatic stress disorder.

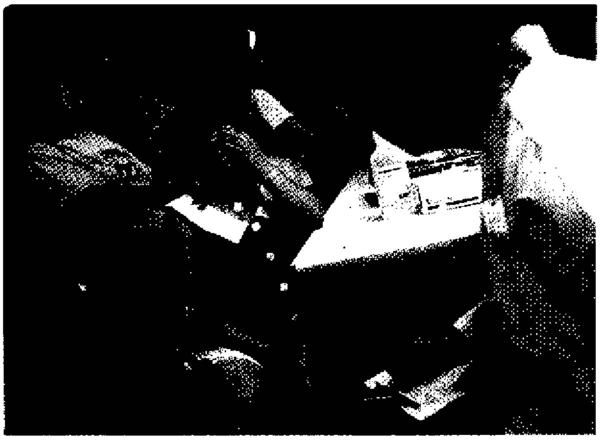
In many respects the emotional responses of and adjustive demands placed on air crash victims are similar to those of victims of natural disasters, such as hurricanes, floods, earthquakes, and volcanic eruptions (Manglesdorff, 1985). A number of special considerations, however, influence the intensity of the problems seen following airplane crashes: Typically airplane crashes are sudden and unexpected; they are usually quite chaotic in terms of their destruction; and air disasters usually occur away from one's familiar settings and with people who are strangers. Consequently, the sense of community that characterizes response to many disasters is lacking. In addition, the impact of an air disaster has a strong emotional irradiation effect; that is, it affects a larger number of people than those immediately involved in the accident itself.

Air disasters differ from natural disasters in another important respect—they usually involve considerable blame and anger that can aggravate or intensify the emotional reactions of survivors even months after the crash. Most airports are required to have a disaster plan that includes rescue and evacuation procedures to deal with an airplane crash. Some airport disaster plans have incorporated a psychological support program to provide emergency mental health services to survivors and the family members of crash victims as well as to rescue workers (Butcher, 1980; Butcher & Dunn, 1989).

These programs are viewed as secondary prevention efforts in that they are aimed at providing emergency psychological services to prevent the development of psychological disorders or to reduce the severity of such problems if they occur. Three types of secondary prevention services have been shown to be effective in dealing with the psychological problems related to air disasters: immediate crisis intervention services to crash survivors and surviving family members; crisis telephone hot-line services to provide information and referrals to victims who lack crisis intervention services; and postdisaster debriefing sessions for secondary victims, such as rescue personnel, affected by the disaster. We will look at each of these services briefly.

*Postdisaster Crisis Therapy.* Timing is critical to crisis intervention, which, when supplied in the immediate aftermath of a disaster, can reduce the emotional distress experienced and can result in a more effective future psychological adjustment (Butcher & Hatcher, 1988; Williams, Solomon, & Bartone, 1988). Crisis intervention treatment involves providing a victim with a supportive, understanding crisis-intervention specialist to enable the victim to express his or her intense feelings about the incident.

Few situations are more intimidating for a mental health professional than to be suddenly asked to treat previously unknown, acutely aggrieved persons—especially those who have just suffered a sudden loss, such as in a disaster. At these times human beings, regardless of their previous level of adjustment, need a great deal more emotional support than traditional mental health professionals normally provide. How do trained crisis counselors help disaster victims manage their emotional distress in the aftermath of a disaster?



*The provision of counseling during the aftermath of a disaster—in this case, the Los Angeles earthquake—has been shown to reduce long-term maladaptive reactions.*

First of all, a crisis counselor provides objective emotional support. The mental health professional must maintain an objective perspective when faced with the intense grief and confusion that accompanies tragedy. It is human for people working with trauma victims to be affected by traumatic events as much as others are. Even hardened rescue personnel such as police officers and fire fighters may become immediately engrossed in and severely affected by the intense loss in an air disaster. The traditionally distant roles of mental health providers are swept away in situations involving loss through disaster. The crisis worker must strive to maintain a balanced perspective to help those involved in the disaster who will be more intensely affected and will have a more diminished perspective. The mental health professional tries to provide a long-term perspective—to allow victims to see that there is hope of surviving psychologically.

A crisis counselor also serves as a source of information and a buffer against misinformation coming from rumor. Disasters are always followed by periods of confusion, misinformation, and negative emotional states. One important role of the mental health professional in disaster response efforts is to obtain, decipher, and clearly communicate to victims the most accurate picture of the situation obtainable at the moment; unfortunately, this may include information of traumatic import to those counseled, such as news that a loved one has been declared dead. The crisis intervention specialist must be knowledgeable about disaster victims' options to provide the information they need for personal decisions.

Finally, a crisis counselor provides practical suggestions to promote adaptation. An important facet of the mental health professional's role in dealing with disaster victims is to guide them through the difficult times by providing a perspective on the problems being faced and by offering valuable guidance for alleviating those problems.

*Crisis Telephone Hot-Line Counseling Services.* After an air disaster, confusion prevails. Airplane disasters always involve considerable psychological turmoil and may produce psychological problems among passengers and crew members. Inaccurate information and anxiety-producing doubts can create a state of tension that results in demoralization and negative behavior, such as absenteeism from work, excessive drinking, and morale problems.

An effective way to deal with this psychological uncertainty and reduce the negative atmosphere following an air disaster is to provide telephone counseling services—an informational hot line of sorts—for all those who feel the need to discuss their concerns, be they airline employees or passenger families. For example, a 24-hour crisis telephone hot-line counseling service was established shortly after the crash of an airliner in Detroit, Michigan, in 1987 in which 156 people died; it continued in operation for four weeks. This service was staffed by qualified psychologists in crisis counseling who provided counseling, information, and referral services.

*Postdisaster Debriefing Sessions.* One goal of a disaster response program is to provide aftercare psychological services to passenger-victims, surviving family members, and rescue personnel. Those who appear to function well at the disaster site may experience difficulties after the immediate crisis has subsided and they have returned to family and normal duties. Even experienced disaster workers who are well trained and effective at the site can be affected later by the pressures and problems experienced during the disaster.

The desire to "unwind" in a psychologically safe environment and to share one's experience of the disaster are universal needs of people following a traumatic situation. Debriefing sessions are designed to provide those who might be directly affected by the accident an opportunity to relate their experiences and to express their feelings and concerns about the disaster. Mitchell (1985) and Keating (1987), for example, have explored the use of debriefing sessions in dealing with emergency workers and found this approach to be effective in reducing the emotional reactions of emergency workers to traumatic events.

Immediate crisis intervention, telephone hot-line counseling, and debriefing programs have become standard efforts following major disasters to help victims and emergency workers return more quickly and effectively to normal functioning. By reducing the impact of a tragedy, these programs attempt to prevent the development of more severe psychological disorders.

## Tertiary Prevention

Tertiary prevention involves efforts aimed at reducing the impact of a disorder and restoring a person to functioning once a mental health problem has been identified. Mental health rehabilitative efforts are important aspects of tertiary prevention and will be discussed in the following sections.

**The Mental Hospital as a Therapeutic Community** Most of the traditional forms of therapy that we discussed in Chapters 16 and 17 may, of course, be used in a hospital setting to promote tertiary prevention. In addition, in many mental hospitals these techniques are being supplemented by efforts to make the hospital environment itself a "therapeutic community" (Gunderson, 1980; Jones, 1953; Paul & Lentz, 1977). That is, all the ongoing activities of the hospital are brought into the total treatment program, and the environment, or milieu, is a crucial aspect of the therapy. This approach is thus often referred to as **milieu therapy.** Three general therapeutic principles guide the milieu approach to treatment:

1. Staff expectations are clearly communicated to patients. Both positive and negative feedback are used to encourage appropriate verbalizations and actions by patients.

2. Patients are encouraged to become involved in all decisions made and all actions taken concerning them. A self-care, do-it-yourself attitude prevails.

3. All patients belong to social groups on the ward. The experience of group cohesiveness gives the patients support and encouragement, and the related process of group pressure helps exert control over their behavior.

In a therapeutic community, as few restraints as possible are placed on patients' freedom, and the orientation is toward encouraging patients to take responsibility for their behavior and to participate actively in their treatment programs. Open wards permit patients to use the grounds and premises. Self-government programs give patients responsibility for managing their own affairs and those of the ward. All hospital personnel are expected to treat the patients as human beings who merit consideration and courtesy. Research has shown that intensive milieu programs significantly benefit even relatively briefly hospitalized patients (Gunderson, 1980).

The interaction among patients—whether in group therapy sessions, social events, or other activities—is planned in such a way as to be of therapeutic benefit. In fact, it is becoming apparent that often the most beneficial aspect of a therapeutic community is the interaction among the patients themselves. Differences in social roles and backgrounds may make empathy between staff and patients difficult, but fellow patients have been there—they have had similar problems and breakdowns and have experienced the anxiety and humiliation of being labeled mentally ill and hospitalized. Thus, constructive relationships frequently develop among patients in a supportive, encouraging milieu.

Another highly successful method for helping patients take increased responsibility for their own behavior is the use of **social-learning programs.** Such programs normally make use of learning principles and techniques, such as token economies, to shape more socially acceptable behavior (Paul, 1979; Paul & Lentz, 1977; Paul & Menditto, 1992; Rhoades, 1981).

A persistent concern with hospitalization is that the mental hospital may become a permanent refuge from the world, either because it offers total escape from the demands of everyday living or because it encourages patients to settle into a chronic sick role with a permanent excuse for letting other people take care of them. The original rationale for the deinstitutionalization policy of recent years was that it would tend to forestall these negative adaptations to hospital confinement. To keep the focus on returning patients to the community and on preventing a return to the institution, contemporary hospital staffs try to establish close ties with patients' families and communities and to maintain a recovery-expectant attitude.

Between 70 and 90 percent of patients labeled as psychotic and admitted to mental hospitals can now be discharged within a few weeks, or at most a few months. Current estimates suggest that there are about 2 to 3 million chronically mentally ill individuals in America, of whom about half reside in mental hospitals and the other half live in nursing homes or in the community (Narrow et al., 1993; Regier et al., 1993; Talbott, 1985; Tien & Eaton, 1992).

Even where disorders have become chronic, effective treatment methods have been developed. In one of the most extensive and well-controlled studies of chronic hospitalized patients, Paul and Lentz (1977) compared the relative effectiveness of three treatment approaches:

1. Milieu therapy, focused on structuring a patient's environment to provide clear communications of expectations, and to get the patient involved in the treatment and participating in the therapeutic community through the group process.

2. A social-learning treatment program, organized around learning principles and using a rigorously programmed token economy system, with ward staff as reinforcing agents. Undesirable behavior was not reinforced, whereas the accumulation of many tokens through effective functioning could result in attractive lifestyle amenities not normally available in public mental hospitals.

3. Traditional mental hospital treatments, including pharmacotherapy, occupational therapy, recreational therapy, activity therapy, and individual or group therapy. No systematic application of milieu therapy or the social-learning program was given to this group.

The treatment project covered a period of six years, with an initial phase of staff training, patient assessment, and baseline recording; a treatment phase; an aftercare phase; and a long (year and a half) follow-up. The changes targeted included resocialization, the learning of new roles, and the reduction or elimination of bizarre behavior. There were 28 chronic schizophrenic patients in each treatment group, matched for age, sex, socioeconomic level, symptoms, and duration of hospitalization. The results of the study were impressive. Both milieu therapy and the social-learning program produced significant improvement in overall functioning and resulted in more successful hospital releases than the traditional hospital care. The behaviorally based social-learning program, however, was clearly superior to the more diffuse program of milieu therapy, as evidenced by the fact that over 90 percent of the released patients from the social-learning program remained continuously in the community, compared with 70 percent of the released patients who had had milieu therapy. The figure for the traditional treatment program was less than 50 percent.

Despite the promise of the token economy approach, emulating as it does certain "real world" principles of exchange the patient will face outside the institution, it has not fared particularly well in terms of public acceptance (Paul & Menditto, 1992). Many feel that it is cruel and inhumane to expect mental patients to govern their behavior in accordance with a prescribed schedule of reinforcements. One might ask in this connection, however, whether it is more humane to consign the patient to the status of a passive and helpless recipient of whatever the environment may somewhat unpredictably have to offer, which in many institutional settings is not very much. Is that truly the message we would wish to convey about the patient's relationship to his or her environment? Probably not, especially in light of the considerable evidence (e.g., Braginsky, Braginsky, & Ring, 1969) that chronic mental patients are as a group surprisingly adept, in fact, at managing outcomes that are within their range of control.

**Aftercare Programs** Even where hospitalization has successfully modified maladaptive behavior and a patient has learned needed occupational and interpersonal skills, readjustment in the community following release may still be difficult. Many studies have shown that in the past up to 45 percent of schizophrenic patients have been readmitted within the first year after their discharge. This is where tertiary prevention can play a major role, especially in terms of providing former clients and patients with supportive services that will help them toward long-term psychological well-being (Paul & Lentz, 1977). Aftercare programs can help smooth the transition from institutional to community life and reduce the number of relapses. Glasscote (1978) found that only 16 percent of patients who received adequate aftercare were readmitted within the first six months compared with 37 percent for patients not receiving aftercare. By the end of five years, more of both groups had been readmitted, but 47 percent of the aftercare group were still in the community, compared with only 30 percent of the group who had not received aftercare.

Aftercare is the responsibility of community mental health facilities and personnel, the community as a whole, and, of course, the person's family. Its goal is to ensure that released patients will be helped to make an adequate readjustment and return to full participation in their home and community with a minimum of delay and difficulty. Sometimes aftercare includes a "halfway" period in which a released patient has a gradual return to the outside world in what were formerly termed halfway houses. Community-based treatment programs, now referred to as aftercare programs, are live-in facilities that serve as a home base for former patients as they make the transition back to adequate functioning in the community. Typically, community-based facilities are run not by professional mental health personnel but by the residents themselves.

*In addition to providing prompt and intense inpatient therapy for patients who need it, tertiary prevention also involves provisions for aftercare, such as this halfway house, to smooth the transition from institutional to community life.*

There is even some evidence that community-based living is preferable to hospital confinement for patients who are still actively psychotic. In a noteworthy program with a group of seriously disturbed mental patients, Fairweather and colleagues (1969, 1980; Fairweather & Fergus, 1993) demonstrated that these patients could function in the community, living in a patient-run facility, even to the extent of responsibly (and profitably) operating a service business. Initially, a member of the research staff coordinated the daily operations of the "Lodge," but he was shortly replaced by a layperson. The patients were given full responsibility for operating the Lodge, for regulating each other's behavior, for earning money, and for purchasing and preparing food. Forty months after their discharge, a comparison was made of these former patients and a comparable group of 75 patients who had been discharged at the same time but had not had the Lodge experience. Whereas most members of the Lodge facility were able to hold income-producing jobs, to manage their daily lives, and to adjust in the outside world, the majority of those who had not had the community group-living experience were unable to adjust to life on the outside and required rehospitalization.

Day hospital facilities within or sponsored by community mental health centers may also be used as alternatives to hospitalization. For example, Penk, Charles, and Van Hoose (1978) showed that partial hospitalization in a day treatment setting resulted in as much improvement (at a lower cost) as full inpatient psychiatric treatment in a group of patients they studied. It would seem, however, that considerable care must be taken in the selection of patients for this less restrictive approach. The risk of untoward consequences, including involvement with the police, may be increased where other social supports are minimal and where patients are prone to substance abuse (Caton et al., 1993).

Similar community-based treatment facilities have been established for alcoholics, drug addicts, and other people attempting to make an adjustment into the community after institutionalization. Such facilities may be said to be specialized in the sense that all residents share similar backgrounds and problems, and this seems to contribute to the facilities' effectiveness.

One of the chief problems of community-based treatment facilities is that of gaining the acceptance and support of community residents (Fairweather, 1994). As Dennes (1974) pointed out in the early years of the growth of community-based treatment, this requires educational and other social measures directed toward increasing community understanding, acceptance, and tolerance of troubled people who may differ somewhat from community norms. The viability of such an approach, however, is demonstrated in the example of Geel, Belgium—"the town that cares"—which we discussed in Chapter 2.

## CONTROVERSIAL ISSUES AND THE MENTALLY DISORDERED

A number of important issues arise related to the legal status of the mentally ill. These issues are the subject matter of **forensic psychology**, or **forensic psychiatry**, and they center on the rights of mental patients and the rights of members of society to be protected from disturbed individuals. For a survey of some of the legal rights that have been gained for the mentally ill over the years, see HIGHLIGHT 18.2.

The issues we will cover in this section are those that have been the center of controversy for many years. We will first review the procedures involved in involuntarily committing disturbed and dangerous individuals to psychiatric institutions. Next, we will turn to the assessment of dangerousness in disturbed persons; we will also discuss a related issue, which has become of key concern to psychotherapists—the court decision that psychotherapists have a duty to protect potential victims of any threatened violence by their patients. In addition, we will examine the controversial insanity defense for capital crimes as well as the issue of deinstitutionalization, or what some have called the premature "dumping" of mental patients into the community. Finally, in the "Unresolved Issues" section we will discuss certain continuing problems that exist at the broad interface where mental health and legal issues come together, problems that are due in part at least to failures of communication and collaboration between the two with respect to challenges they share.

### The Commitment Process

Persons with psychological problems or behaviors that are so extreme and severe as to pose a threat to themselves or others may require protective confinement. Those who commit crimes, whether or not they have a psychological disorder, are dealt with primarily through the judicial system—arrest, court trial, and, if convicted, possible confinement in a penal institution. Persons who are judged to be potentially dangerous because of their psychological state may, after civil commitment procedures, be confined in a mental institution. The steps in the commitment process vary slightly depending on state law (we will here use Minnesota as our model), the locally available community mental health resources, and the nature of the problem—for example, commitment procedures for a mentally retarded person will be different from those for a person with an alcohol-abuse problem.

A distinction should be made here between voluntary hospitalization and involuntary commitment. In most cases, people enter mental institutions without a court order; that is, they accept voluntary commitment or hospitalization. In these cases, they can, with sufficient notice, leave the hospital if they wish. In cases in which a person is believed to be dangerous or unable to provide for his or her own care, the need for involuntary commitment may arise.

Being mentally ill is not sufficient grounds for placing a person in a mental institution against his or her will. Although procedures vary somewhat from state to state, several conditions beyond mental illness usually must be met before formal commitment can occur (Schwitzgebel & Schwitzgebel, 1980). In brief, the person must be judged to be:

18.2

## Patient Advocacy: Important Court Decisions Regarding Patient Rights

Several important court decisions in recent years have helped establish certain basic rights for individuals suffering from mental disorders, but have also curtailed these rights with continuing controversy:

*Right to treatment.* In 1972, a U.S. District Court in Alabama made a landmark decision in the case of *Wyatt* v. *Stickney.* The ruling held that a mentally ill or mentally retarded person had a right to receive treatment. Since the decision, the state of Alabama has increased its budget for the treatment of mental health and mental retardation by 300 percent.

*Freedom from custodial confinement.* In 1975, the U.S. Supreme Court upheld the principle that patients have a right to freedom from custodial confinement if they are not dangerous to themselves or others and if they can safely survive outside of custody. In the *Donaldson* v. *O'Connor* decision, the defendants were required to pay Donaldson $10,000 for having kept him in custody without providing treatment.

*Right to compensation for work.* In 1973, a U.S. District Court ruled in the case of *Souder* v. *Brennan* (the secretary of labor) that a patient in a nonfederal mental institution who performed work must be paid according to the Fair Labor Standards Act. Although a 1978 Supreme Court ruling nullified the part of the lower court's decision dealing with state hospitals, the ruling still applied to mentally ill and mentally retarded patients in private facilities.

*Right to live in a community.* In 1974, the U.S. District Court decided, in the case of *Staff* v. *Miller,* that released state mental hospital patients had a right to live in "adult homes" in the community.

*Right to less restrictive treatment.* In 1975, a U.S. District Court issued a landmark decision in the case of *Dixon* v. *Weinberger.* The ruling established the right of individuals to receive treatment in less restrictive facilities than mental institutions.

*Right to legal counsel at commitment hearings.* The State Supreme Court of Wisconsin decided in 1976, in the case of *Memmel* v. *Mundy,* that an individual had the right to legal counsel during the commitment process.

*Right to refuse treatment.* Several court decisions have provided rulings and some states have enacted legislation permitting patients to refuse certain treatments, such as electroconvulsive therapy and psychosurgery.

*The need for confinement must be shown by clear, convincing evidence.* In 1979, the U.S. Supreme Court ruled, in the case of *Addington* v. *Texas,* that a person's need to be kept in an institution must be based on demonstrable evidence.

*Limitation on patients' rights to refuse psychotropic medication.* In 1990 the U.S. Supreme Court ruled, in *Washington* v. *Harper,* that a Washington state prison could override a disturbed prisoner's refusal of psychotropic medications, based on a finding that the prison's review process adequately protected the patient's rights. We see in this instance that changes in the national political climate can reverse prior trends appearing to favor patients' rights.

Based on Bernard (1979); Hermann (1990); National Association for Mental Health (1979); and Mental Health Law Project (1987).

- Dangerous to himself or herself, or to others
- Incapable of providing for his or her basic physical needs
- Unable to make responsible decisions about hospitalization
- And/or in need of treatment or care in a hospital

The use of the "dangerousness" complaint as grounds for civil commitment has apparently increased in recent years (McNeil & Binder, 1986). Typically, filing a petition for a commitment hearing is the first step in the process of committing a person involuntarily. This petition is usually filed by a concerned person, such as a relative, physician, or mental health professional. When a petition is filed, a judge appoints two examiners to evaluate the "proposed patient." In Minnesota, for example, one examiner must be a physician (not necessarily a psychiatrist); the other can be a psychiatrist or a psychologist. The patient is asked to appear voluntarily for psychiatric examination before the commitment hearing. The hearing must be held within 14 days, which can be extended for 30 more days if good cause for the extension can be shown. The law requires that the court-appointed examiners interview the patient before the hearing.

If a person is committed to a mental hospital for treatment, the hospital must report to the court within 60 days as to whether the person needs to be confined even longer. If no report is given by the hospital, the patient must be released. If the hospital indicates that the person needs further treatment, then the commitment period becomes indeterminate, subject to periodic reevaluations.

Because the decision to commit a person is based on the conclusions of others about the person's capabilities and his or her potential for dangerous behavior, the civil commitment process leaves open the possibility of the unwarranted violation of a person's civil rights. As a consequence, most states have stringent safeguards in the procedures to assure that any person who is the subject of a petition for commitment is granted due process, including rights to formal hearings with representation by legal counsel. If there is not time to get a court order for commitment or if there is imminent danger, however, the law allows emergency hospitalization without a formal commitment hearing. In such cases, a physician must sign a statement saying that an imminent danger exists. The patient can then be picked up (usually by the police) and detained under a "hold order," usually not to exceed 72 hours, unless a petition for commitment is filed within that period.

Involuntary commitment in a psychiatric facility is, in large part, contingent on a determination that a person is dangerous and needs to be confined out of a need to protect himself or herself or society. We will now turn to the important question of evaluating patients in terms of their potential dangerousness.

## The Assessment of "Dangerousness"

As we have seen, though most psychiatric patients are not considered dangerous and need no special safety precautions, some are violent and require close supervision—perhaps confinement until their dangerousness is no longer a problem. Few psychiatric patients are assaultive at or prior to their admission to psychiatric facilities. Rates of assaultiveness vary from setting to setting, though in all reported studies the number of assaultive patients is relatively low. Nevertheless, the issue, involving as it does life and death considerations, deserves the most careful scrutiny as to *any* enhanced risk of violence mental disorders may entail. Fortunately, the question of the overall relationship between violence and mental disorder, one that is far more complex than may appear, has been competently and thoroughly addressed in a recent review by Monahan (1992). He summarizes his findings as follows:

> Whether the measure is the prevalence of violence among the disordered or the prevalence of disorder among the violent, whether the sample is people who are selected for treatment as inmates or people randomly chosen from the open community, and no matter how many social and demographic factors are statistically taken into account, there appears to be a relationship between mental disorder and violent behavior. Mental disorder may be a robust and significant factor for the occurrence of violence, as an increasing number of clinical researchers in recent years have averred. . . ." (p. 519)

Monahan (1992) goes on to note, however, that policy implications and implications pertaining to the social image of former mental patients and the manner in which these are managed in the media must be tempered by two additional and well-established findings: (a) the increased risk of violence appears limited to persons who are *currently experiencing* psychotic symptoms, and (b) *approximately 90 percent of all currently disordered persons show no propensity toward violence.*

The determination that a patient is potentially dangerous is a difficult one to make (Litwack & Schlesinger, 1987). A 43-year-old homeless Cuban refugee, for example, who had only a few days earlier undergone a psychiatric evaluation and been released, stabbed two tourists to death on the Staten Island Ferry because "God told him to kill" (*Time,* July 21, 1986). Westley Allan Dodd, condemned molester, mutilator, and murderer of numerous children, by his own admission continued undetected in his violent crimes during the several periods of therapy he underwent by court order (*Time,* January 11, 1993). Obviously, determining potential dangerousness is a crucial judgment for mental health professionals to make—not only from a therapeutic standpoint, to assure that the most appropriate treatment is conducted, but also from the legal point of view of responsibility to the larger society. A clinician has a clear responsibility to attempt to protect the public from potential violence or other uncontrolled behavior of dangerous patients. A dramatic incident of a failure to assess the extent of a patient's dangerousness was reported by Gorin (1980, 1982) on the television news program *60 Minutes:*

*Juan Gonzalez stabbed and killed two people and injured nine others on the Staten Island Ferry. A few days before the incident, Gonzalez had undergone psychiatric evaluation after making wild death threats on the street. Though doctors concluded that he had a psychotic paranoid disorder, Gonzalez was released after two days because there was not enough space at the facility and he could not be involuntarily committed to a mental institution.*

In December, 1979, Mrs. Eva B. was brutally stabbed to death by her former husband while a police dispatcher listened to her terrified screams over the telephone. Only hours before the stabbing incident occurred, Mr. B., who had attacked Mrs. B. eight times in the past, had been judged by two staff psychiatrists not to be dangerous. He had then been released, as part of his treatment, on a temporary pass from the Pilgrim State Hospital in New York. The hospital staff had released Mr. B. from confinement at this time despite the fact that both the judge and the prosecuting attorney who had been involved in his trial (for attempting to kill his wife) had independently written the New York State Department of Mental Health recommending that Mr. B. be held in the strictest confinement because of his persistent threats against Mrs. B. (Indeed, on two previous occasions, Mr. B. had escaped from the hospital and attempted to kill her.) The judge and attorney had also recommended that Mrs. B. should be warned if Mr. B. was released. Ironically, six hours after she had been murdered, a telegram from the hospital was delivered to Mrs. B.'s home warning her that her husband had not returned from his pass.

Looking beyond what appears to be some failure to follow through on the court's recommendations, this case illustrates a number of difficult yet critical dilemmas involved in trying to identify or predict dangerousness in psychiatric patients. First, it emphasizes the fact that some people are capable of uncontrolled violent behavior and hence are potentially dangerous if left unsupervised in the community. It also reflects the dilemma faced by mental health professionals who, attempting to rehabilitate disturbed patients by gradually easing them back into society, must exhibit some degree of trust in these individuals. Finally, and critically, it illustrates the fact that it is very difficult—for professionals and laypersons alike—to accurately appraise "dangerousness" in some individuals.

**Attempts to Predict Dangerousness** It is usually an easy matter to determine, after the fact, that a person has committed a violent act or acts and has demonstrated "dangerous behavior." The difficulty comes when one attempts to determine in advance if the person is going to commit some particular violent act. Assessing a general state of "dangerousness" is not the same thing as the far more formidable task of predicting whether a designated violent act will occur. How well do mental health professionals do in predicting the occurrence of dangerous acts? A general answer to this question would have to be "not very well," but there are several problems to be considered in coming to an adequate appreciation of the difficulties of the task. Perhaps the foremost is that the definition of what is "dangerous" is itself unclear. It turns out to depend, to a large extent, on who is asked. Some people have a limited or restrictive definition of what behaviors are dangerous and are willing to tolerate more aggressive behavior than others, who in turn view a broader range of behaviors as potentially dangerous. There is of course a consensus about the dangerousness of extreme behaviors such as murder and assault with a deadly weapon, but as we move away from such obvious cases public consensus tends to fade rather rapidly. Rape, for example, has only recently attained the serious criminal status it is now usually accorded, but even here there are local pockets of resistance in which rape is still (erroneously) considered to be an inconsequential and excusable infraction having little or no predictiveness as to "real" violence (see Segal & Stermac, 1990).

Violent acts are particularly difficult to predict because they are apparently determined as much by situational circumstances as they are by an individual's personality traits or violent predispositions. It is, of course, impossible to predict with any great certainty what environmental circumstances are going to occur or what particular circumstances will provoke or instigate aggression for any given violently disposed person. One obvious and significantly predictive risk factor is a past history of violence (Megargee, 1993; Noble & Rodger, 1989), but clinicians are not always able to unearth this type of background information.

As already noted, some types of patients, particularly actively schizophrenic and manic individuals (Binder & McNiel, 1988) or patients with well-entrenched delusions (de Pauw & Szulecka, 1988), are far more likely to commit violent acts than the average for the mental patient group as a whole. Martell and Dietz (1992) have recently reported a study of persons convicted of pushing or attempting to push unsuspecting victims, about half of whom were killed or seriously injured, into the paths of trains approaching subway stations in New York City. Most of the perpetrators of this gruesome crime, whose incidence has risen in recent years, were both psychotic and homeless at the time of the act.

Mental health professionals typically err on the conservative side when assessing "violence proneness" in a patient; that is, they overpredict violence. They consider some individuals more dangerous than they actually are and, in general, predict a greater percentage of clients to be dangerous, requiring protective confinement, than actually become involved in violent acts (Megargee, 1995; Monahan, 1981). Such a trend is of course quite understandable from the standpoint of the practitioner, considering the potentially serious consequences of a "false negative" judgment. It is likely, however, that many innocent patients thereby sustain a violation of their civil rights. Given a certain irreducible level of uncertainty in the prediction of violence, it is not obvious how this dilemma can be completely resolved.

**Methods for Assessing Potential for Dangerousness** Evaluating a person's potential for committing violent acts is difficult because only part of the equation is available for study:

$$\begin{array}{l} \text{predisposing personality} \\ \underline{+\ \text{environmental instigation}} \\ =\ \text{aggressive act} \end{array}$$

As we have noted, psychologists and psychiatrists usually do not know enough about the environmental circumstances the person will encounter to evaluate what the instigation to aggression will be. Predictions of dangerousness focus, then, primarily on aspects of the individual's personality.

The two major sources of personality information are data from personality tests and the individual's previous history. Personality testing can reveal whether the individual shows personality traits of hostility, aggressiveness, impulsiveness, poor judgment, and so on. Notwithstanding the already noted readiness of practitioners to predict the likelihood of violence based on such factors, many individuals having these characteristics never do act on them. The use of previous history—such as having committed prior aggression, having verbalized threats of aggression, having an available means of committing violence (such as possession of a gun), and so on—are useful predictors (Monahan, 1981). Like personality testing, however, these data only focus on the individual factors and do not account for the situational forces that impinge on the person, which may include notably provocative behavior on the part of the victim (Megargee, 1993).

The prediction of violence is even more difficult in the case of an overcontrolled offender, one of whose more salient characteristics is a subaverage level of manifestly aggressive behavior prior to the commission of an aggressive act, very often an extremely violent one. Megargee (1970) studied extensively the "overcontrolled hostile" person who is the epitome of well-controlled behavior but who, typically on only one occasion, loses control and murderously attacks another person. Examples of this type of killer are dramatic: the high school honor student, reportedly civic-minded and fond of helping sick and old people, who is arrested for torturing and killing a three-year-old girl in his neighborhood; or the mild, passive father of four who loses his temper over being cheated by a car dealer and beats the man to death with a tire iron. These examples illustrate the most difficult type of aggressive behavior to predict—the sudden, violent, impulsive act of a seemingly well-controlled and "normal" individual.

A general pessimism has prevailed in recent years about our ability to predict dangerousness. Several studies in violence prediction, however, have attempted to improve prediction by identifying persons at risk for violence. Using demographic data on family background, history of violence, friendships, and substance use, Klassen and O'Connor (1988) were able to identify 76 percent of the people who later became violent. They concluded that predictive assessments could be improved even more if the context in which violence occurs is taken into consideration.

**The Duty to Protect: Implications of the Tarasoff Decision** What should a therapist do on learning that one of his or her patients is planning to harm one or more other persons? Can the therapist violate the legally sanctioned confidence of the therapy contract and take action to prevent the patient from committing the act? Today in probably most of the states the therapist not only can violate confidentiality with impunity but may be required by law to do so—that is, to take action to protect persons from the threat of imminent violence against them. In its original form, this requirement was conceived as a duty to warn the prospective victim. The duty-to-warn legal doctrine was given a great deal of impetus in a California court ruling in the case of *Tarasoff* v. *The Regents of the University of California et al.* (Mills, Sullivan, & Eth, 1987).

In this case, Prosenjit Poddar was being seen in outpatient psychotherapy by a psychologist at the university mental health facility. During his treatment, Mr. Poddar indicated that he intended to kill his former girlfriend, Tatiana Tarasoff, when she returned from vacation. The psychologist, concerned about the threat, discussed the case with his supervisors, and they agreed that Mr. Poddar was dangerous and should be committed for further observation and treatment. They informed the campus police, who picked up Mr. Poddar for questioning. The police judged Mr. Poddar to be rational and released him after he promised to leave Ms. Tarasoff alone. Mr. Poddar then terminated treatment with the psychologist. About two months later, he stabbed Ms. Tarasoff to death. Her parents later sued the University of California and its staff involved in the case for their failure to hospitalize Mr. Poddar and their failure to warn Ms. Tarasoff about the threat to her life. In due course the California Supreme Court in 1974 ruled that the defendants were not liable for failing to hospitalize Mr. Poddar; it did, however, find them liable for their failure to warn the victim. Ironically, Prosenjit Poddar, the criminal, was released on a trial technicality and returned home to India. In a later analysis of the case, Knapp (1980) said that the court

> ruled that difficulty in determining dangerousness does not exempt a psychotherapist from attempting to protect others when a determination of dangerousness exists. The court acknowledged that confidentiality was important to the psychotherapeutic relationship but stated that the protective privilege ends where the public peril begins. (p. 610)

The duty-to-warn ruling in the **Tarasoff decision,** while spelling out a therapist's responsibility in situations where there has been an explicit threat on a specific person's life, left other areas of application unclear. For example, does this ruling apply in cases where a patient threatens to commit suicide, and how might the therapist's responsibility be met in such a case? What if anything should a therapist do when the object of violence is not clearly named, such as when global threats are made? Would the duty-to-warn ruling hold up in other states? Or might deleterious effects on patient-therapist relationships outweigh any public benefit to be derived from the duty to warn? Responding to mounting pressures for clarification, chiefly from mental health professional organizations, the California Supreme Court issued a revised opinion in 1976, called *Tarasoff II.* In this decision the Court ruled that the duty was to *protect,* rather than specifically to warn, the prospective victim, but it left vague the question of how this duty might be discharged—presumably in order to provide practitioners with enhanced latitude in dealing with danger to third parties. However, the granting of such latitude would seem to carry with it the possibility of being held liable for providing inadequate protection based on rules not yet formulated at the time intervention is contemplated, as was the problem for the original *Tarasoff* defendants. Meanwhile, numerous other lawsuits in other jurisdictions had been filed and had been adjudicated in inconsistent and confusing ways (Mills et al., 1987).

The many perplexing issues for practitioners left in the wake of *Tarasoff* were partly resolved, at least in California, by the legislature's adoption in 1985 of a new state law essentially establishing that the duty to protect is discharged if the therapist makes "reasonable efforts" to inform potential victims *and* an appropriate law enforcement agency of the pending threat. In other jurisdictions, however, the inconsistent judicial fallout from *Tarasoff* has continued and has been a source of much anxiety and confusion among mental health professionals, many of whom continue to believe on ethical and clinical grounds that strict confidentiality is an absolute and inviolable trust. A small minority of states, for example, Maryland and Pennsylvania, has explicitly affirmed the latter position, repudiating *Tarasoff* altogether (Mills et al., 1987). Official professional ethics codes, such as that of the American Psychological Association (1992), normally compel compliance with relevant law regardless of personal predilections to the contrary. Where the law is itself vague or equivocal, however, as it often is in this area, there is of course much room for idiosyncratic and biased interpretation.

No uniformly applicable, national resolution of the problem is evident as of this writing. Until one becomes available, clinicians would be well advised to follow closely systematic and preferably written protocols for staged responses to the varying levels of explicitness and imminence contained in client threats of violence, and to carefully document and justify, again in writing, their decisions for actions taken (Gross et al., 1987). An analysis of adjudicated court cases undertaken by Mills (1984) suggests that the judgment of practitioner liability as a practical matter usually turns on the degree of *foreseeability* of the violence directed at explicitly designated victims.

## The Insanity Defense

> The picture in the February 13, 1992, issue of *Time* said it all. The largest frame offered Jeffrey Dahmer, on trial for the murder, dismemberment, and cannibalization of 15 men in Milwaukee. The top right-hand frame pictured David Berkowitz, the "Son of Sam," who terrorized New York City for 13 months in 1976–1977 while killing six people and wounding seven others. The bottom right-hand frame showed John Hinckley, the would-be assassin of President Ronald Reagan in 1981. (Steadman et al., 1993, p. 1)

What linked the three infamous persons named here, apart from their murderous exploits, was their shared claim that they were in fact not legally responsible for their criminal acts—that is, each attempted to use the so-called **insanity defense** ("not guilty by reason of insanity") as a means of avoiding the legally prescribed consequences of their crimes. In technical legal terms, in other words, these men were invoking the ancient doctrine that their acts, while guilty ones (*actus rea*), lacked moral blameworthiness because they were unaccompanied by the corresponding (and, for a guilty judgment, legally mandated) intentional state of mind (*mens rea*)—the underlying assumption being that "insanity" somehow precludes or absolves the harboring of a guilty intent. Whatever the operational and conceptual conundrums involved in this doctrine—and these on the face of it would appear to be legion—they were rendered moot in the Dahmer and Berkowitz cases because the planned insanity defenses proved unsuccessful, as is the usual outcome (Steadman et al., 1993).

The outcome of the Hinckley case was different in a number of important respects, at base because in this instance the insanity defense was successful. Hinckley pleaded "not guilty by reason of insanity" (NGRI) at trial, and in June of 1982 was acquitted on those grounds. His acquittal immediately unleashed a storm of public protest and of widespread, often unduly hasty attempts to reform the law pertaining to the NGRI defense so as to make it a less-attractive option to capital case defendants and their attorneys. Hinckley himself was committed to the care of a federally operated high-security mental hospital, ostensibly to be involuntarily retained there until such time as his disorder remits sufficiently that his release would not constitute a danger to himself or others. He remains incarcerated at this writing, and it seems doubtful that he will be declared sufficiently "well" to be "discharged" any time in the foreseeable future. His release would almost certainly bring forth another public outcry demanding abolition or limitation of the insanity defense. In our judgment, there is in all of this arrangement a certain unsatisfactorily indirect and disingenuous quality, one perhaps encouraged by a persistent failure of legal scholars to examine critically and rigorously the guilt-absolving insanity construct and the *mens rea* doctrine from which it derives.

In any event, in recent years the use of the NGRI defense in capital crime trials has been surrounded by controversy, largely owing to the uproar created by the outcome of the Hinckley trial (Steadman et al., 1993). Public concern, especially in cases of high

*The use of the insanity defense in highly publicized cases, such as John Hinckley's assassination attempt on President Reagan in 1981, has led to controversy over whether it legitimately protects a mentally ill offender's rights or is a contrivance to avoid criminal responsibility.*

visibility, that guilty (in the *actus rea* sense) defendants may feign mental disorder and fraudulently profit from this plea in avoiding criminal responsibility is evidently never far beneath the surface. Good defense attorneys are of course aware of this public cynicism, which is likely to be shared by juries, and attempt to counteract it in various ways, often by portraying their purportedly "insane at the time of the act" clients to have been themselves at an earlier time victims of extraordinarily heinous and traumatic acts. Some of them undoubtedly were, but the strategy of creating sympathy while offering a plausible reason for the "insane" act would have a compelling attraction in any case.

Despite some features that make it an appealing option to consider, especially where the undisputed facts are strongly aligned against the defendant, the NGRI defense has actually been employed quite rarely—in less than 2 percent of capital cases in the United States over time (Fersch, 1980; Steadman et al., 1993). Studies have confirmed the fact, however, that persons acquitted of crimes by reason of insanity spend less time, on the whole, in a psychiatric hospital than persons who are convicted of crimes spend in prison (Kahn & Raifman, 1981; Pasewark, Pantle, & Steadman, 1982).

To this point in the discussion, we have used the term "insanity defense" loosely, which is anathema to actual legal practice; we must now become more attentive to the many more precise legal nuances involved. Established precedents defining the insanity defense are as follows:

1. *The M'Naughten Rule (1843).* Under this ruling, people are believed to be sane unless it can be proved that, at the time of committing the act, they were laboring under such a defect of reason (from a disease of the mind) that they did not know the nature and quality of the act they were doing—or, if they did know they were committing the act, they did not know that what they were doing was wrong.

2. *The irresistible impulse rule (1887).* A second precedent in the insanity defense is the doctrine of the "irresistible impulse." This view holds that accused persons might not be responsible for their acts, even if they knew that what they were doing was wrong (according to the M'Naughten Rule), if they had lost the power to choose between right and wrong. That is, they could not avoid doing the act in question because they were compelled beyond their will to commit the act (Fersch, 1980).

3. *The Durham Rule.* In 1954, Judge David Bazelon, in a decision of the U. S. Court of Appeals, broadened the insanity defense further. Bazelon did not believe that the previous precedents allowed for a sufficient application of established scientific knowledge of mental illness and proposed a test that would be based on this knowledge. Under this rule, the accused is "not criminally responsible if his or her unlawful act was the product of mental disease or mental defect." New Hampshire, where this standard originated, is presently the only state subscribing to it.

4. *The American Law Institute (ALI) standard (1962).* This test combines the cognitive aspect of M'Naughten with the volitional focus of irresistible impulse in holding that the perpetrator is not legally responsible if at the time of the act he or she, owing to mental disease or defect, lacked "substantial capacity" either to appreciate its criminal character or to conform his or her behavior to the law's requirements.

5. *The Federal Insanity Defense Reform Act (IDRA).* Adopted by Congress in 1984 as the standard regarding the insanity defense to be applied in all federal jurisdictions, this act abolished the volitional element of the ALI standard and modified the cognitive one to read "unable to appreciate," thus bringing the definition quite close to M'Naughten. IDRA also specified that the mental disorder involved must be a severe one, and shifted the burden of proof from the prosecution to the defense; that is, the defense must clearly and convincingly establish the defendant's insanity, as opposed to the prior requirement that the prosecution clearly and convincingly demonstrate the defendant to have been sane when the prohibited act was committed.

This shifting of the burden of proof for the insanity defense, by the way, was an extremely common reform instituted by the states in the wake of protests of excessive laxity provoked by the Hinckley acquittal. Like the many other types of reform proposed at that time, the intent was to discourage use of the insanity defense and to make its success improbable if it *were* used. Unlike the average reform instituted, this one proved quite effective in altering litigation practices in the intended direction, according to the extensive data gathered by Steadman and colleagues (1993).

At the present time, nearly all of the 50 states and the District of Columbia subscribe to a version of either the ALI or the more restrictive M'Naughten standard. Three states—Idaho, Montana, and Utah—have entirely abolished the attribution of insanity as an acceptable defense for wrongdoing, a somewhat draconian solution that compensates in clarity for what some feel it lacks in compassion.

New York is a special case. While it uses a version of M'Naughten to define insanity, with the burden of proof on the defense, an elaborate procedural code has been enacted whose effect is to promote fairness in outcomes while ensuring lengthy and restrictive hospital commitment for defendants judged to be dangerous; it appears to have worked well (Steadman et al., 1993).

As we have seen, with the expansion of the diagnostic classification of mental disorder, a broad range of behaviors can be defined as mental disease or defect. Which mental diseases serve to excuse a defendant from criminal responsibility? Generally, under M'Naughten, psychotic disorders were the basis of the insanity defense, although that would appear an arguable proposition; but under the Durham or ALI Rules other conditions (such as personality disorder or dissociative disorder) might also apply. How, then, is guilt or innocence determined? Many authorities believe that the insanity defense requires of the courts an impossible task—to determine guilt or innocence by reason of insanity on the basis of psychiatric testimony. In many cases, this has involved conflicting testimony because both the prosecution and the defense have "their" panel of expert psychiatric witnesses, who typically are in complete disagreement (Fersch, 1980; Marvit, 1981). From a certain point of view, of course, the question such experts are asked to resolve is fundamentally unanswerable; it may even be meaningless in the sense that no conceivable empirical observation could unequivocally decide, after the fact, whether the defendant's mental state at the time of the crime was exculpatory by any rule of law so far proposed, or indeed imaginable.

It may well be, therefore, that the notion of exculpation by reason of insanity, while defensible and humane in some abstract sense, is so basically flawed conceptually and procedurally that we are in need of a serious rethinking of the entire matter. Meanwhile, it would seem wise to employ stringent standards for the insanity defense, such as the federal IDRA rules or the relevant and carefully considered statutory procedures enacted in New York State (see Steadman et al., 1993, for details).

Finally, it should be noted that several states have adopted the optional plea/verdict of "guilty but mentally ill" (GBMI). In these cases, a defendant may be sentenced but placed in a treatment facility rather than in a prison. This two-part judgment serves to prevent the type of situation in which a person commits a murder, is found not guilty by reason of insanity, is turned over to a mental health facility, is found to be rational and in no further need of treatment by the hospital staff, and is unconditionally released to the community after only a minimal period of confinement. Under the two-part decision, such a person would remain in the custody of the correctional department until the full sentence is served. Marvit (1981) has suggested that this approach might "realistically balance the interest of the mentally ill offender's rights and the community's need to control criminal behavior" (p. 23). However, in Georgia, one of the states adopting this option, GBMI defendants received longer sentences and longer periods of confinement than those pleading NGRI and losing. Overall, outcomes from use of the GBMI standard, often employed in a plea-bargaining strategy, have been disappointing (Steadman et al., 1993).

## Deinstitutionalization

As we learned in Chapter 2, public asylums or mental hospitals were originally viewed as the most humane settings for dealing with chronic patients; many of these institutions were originally operated according to the benign and gentle principles of "moral therapy." The people who founded the institutions and the society that supported them saw these facilities as havens for retarded or disturbed individuals who could not survive in the world on their own. Ironically, though, and coincident with huge and successive waves of immigrants arriving on our shores beginning in the later nineteenth century, hospitals gradually became overcrowded, hospital staffs overworked, and taxpayers increasingly restive about escalating costs; over time patient care deteriorated to a point that probably had never before been seen in America.

Mental hospitals, founded out of a concern for human welfare, came to be viewed as horrid places where humane care was far more a proclaimed philosophy than a practical reality. Bassuk and Gerson (1978) noted that, "the reform movement [of the late nineteenth and early twentieth centuries], having seen its original objectives apparently accomplished, had ceased to be a significant influence" (p. 47).

By the 1940s the network of state mental hospitals, once proudly hailed as a superb example of humanitarianism toward the helpless and "hopelessly insane" (so it was conceived) creatures incarcerated within their high walls, had become "The Shame of the States" (Deutsch, 1948). On average, they were dreadfully neglected, demoralized places, bureaucratically administered by nonpsychiatrist physicians, many of them so lacking in personal and professional skills that they could not otherwise maintain gainful employment. Physical abuse of patients was common, sometimes under the guise of cruel "treatments" such as "regressive" ECT (multiple electrically induced convulsions per day), straitjackets, and various forms of "hydrotherapy" (e.g., "wet packs" and lengthy, restrained immersion in laced-canvas-covered tubs). Psychological abuse, needless to say, was routine (Goffman, 1961).

Coincident with the introduction of the phenothiazine class of antipsychotic drugs in the mid-1950s and with the newer and more optimistic attitudes prevailing among mental health professionals trained after World War II, this sorry state of affairs had begun to change. By then, however, mental hospitals and mental hospitalization had acquired very unsavory reputations, reinforced by an abysmal performance record in terms of discharge rates (Bockhoven, 1972). An increasingly intense and widespread disenchantment with the by now often very large and growing state mental hospitals became, by the 1960s, impossible for governmental officials to ignore. Many authorities, not without ample corroborating evidence, concluded that these institutions were serving primarily as substandard human "warehouses" for the mentally impaired, and that they dehumanized individuals rather than helped them resolve their problems and return to society.

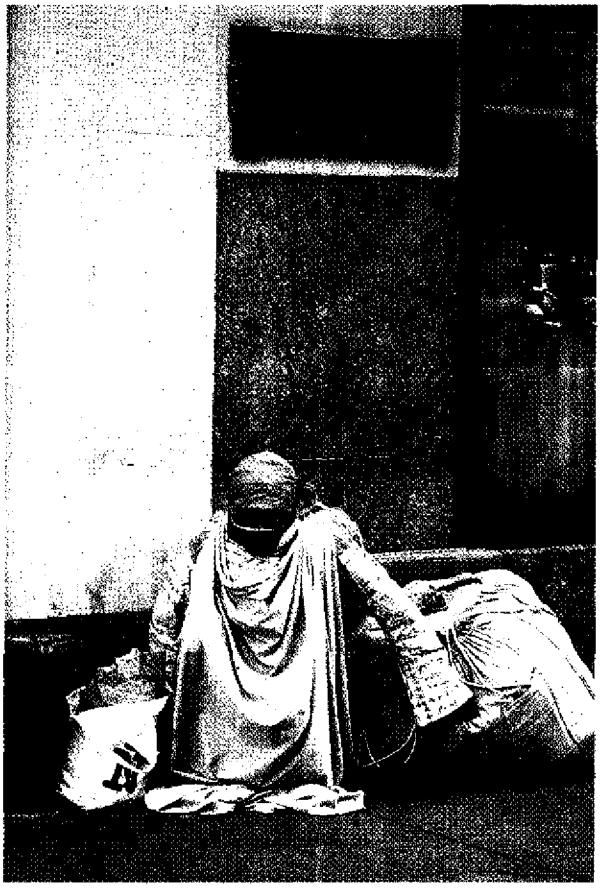
Mental hospital reformers saw this growing movement as an opportunity to rid society of an unwelcome evil; hospital administrators and staff members initially viewed it as a way of lowering the patient census to manageable numbers; and state governments viewed the movement with favor because it allowed legislatures (ever concerned about budgets) to reduce state spending. Many reformers recommended that some state mental hospitals be permanently closed and their residents either placed in more humane facilities or returned to their families and communities (Bachrach, 1976). In fact, in a number of cases, the courts summarily ordered closure of some particularly offensive institutions.

Paralleling these developments was the effort, on the part of the federal government and many concerned people, to develop expanded community resources to provide chronic patients with continued psychiatric care in their local communities. Supporters of this effort believed then—and many do now—that society should be able to integrate these people back into the community and treat those who must remain with the least restrictive alternative. This movement, referred to in the aggregate as **deinstitutionalization,** has become today the source of yet another raging controversy in the mental health field. Some authorities consider the emptying of the mental hospitals to be a positive expression of society's desire to free previously confined persons, while others speak of the "abandonment" of chronic patients to a cruel and harsh existence, which for many includes homelessness. Many citizens, too, complain of being harassed, intimidated, and frightened by obviously disturbed persons wandering the streets of their neighborhoods. The problems are real enough, but they have come about to a large extent because the planned community efforts to fill the gaps in service never really materialized at effective levels (Grob, 1994).

There has indeed been a significant reduction in state and county mental hospital populations, from over a half million in 1950 (Lerman, 1981) to about 100,000 in recent years (Narrow et al., 1993); these figures are all the more impressive in proportional terms, inasmuch as the U.S. population grew by nearly 100 million in the intervening years. A number of factors have interacted to alter the pattern of mental hospital admissions and discharges over the past 40 years. As has been noted in previous chapters, the introduction of the antipsychotic drugs made it possible for many patients who would formerly have required confinement to be released into the community. The availability of these drugs led many to believe (falsely) that all mental health problems could be managed with medication. In addition, the changing treatment philosophy and the desire to eliminate mental institutions was accompanied by the belief that society wanted and could financially afford to provide better community-based care for chronic patients outside of large mental hospitals.

In theory, the movement to close the public mental hospitals seemed workable. According to plan, many community-based mental health centers would be opened and would provide continuing care to the residents of hospitals after discharge. Residents would be given welfare funds (supposedly costing the government less than it takes to maintain large mental hospitals) and would be administered medication to keep them stabilized until they could obtain continuing care. Many patients would be discharged to home and family, while others would be placed in smaller, homelike board-and-care facilities or nursing homes.

Many unforeseen problems arose, however. Many residents of mental institutions had no families or homes to go to; board-and-care facilities were often substandard; the community mental health centers were ill-prepared and insufficiently funded to provide needed services for chronic patients, particu-



*Some homeless people, casualties of indiscriminate deinstitutionalization, are seriously mentally disordered.*

larly as national funding priorities shifted during the 1980s (Humphreys & Rappaport, 1993); many patients had not been carefully selected for discharge and were not ready for community living; and many of those who were discharged were not followed up sufficiently or with enough regularity to ensure their successful adaptation outside the hospital. Indeed, countless patients were discharged to fates that were even more dehumanizing than the conditions in any of the hospitals (Westermeyer, 1987). The following case illustrates the situation:

Dave B., age 49, had been hospitalized for 25 years in a state mental hospital. When the hospital was scheduled for phaseout, many of the patients, particularly those who were regressed or aggressive, were transferred to another state hospital. Dave was a borderline mentally retarded man who had periodic episodes of psychosis. At the time of hospital closing, however, he was not hallucinating and was "reasonably intact." Dave was considered to be one of the "less disturbed" residents because his psychotic behavior was less pronounced and he presented no dangerous problems.

He was discharged to a board-and-care facility (actually an old hotel whose clientele consisted mostly of former inpatients). At first, Dave seemed to fit in well at the facility; mostly he sat in his room or in the outside hallway, and he caused no trouble for the caretakers. Two weeks after he arrived, he wandered off the hotel grounds and was missing for several days. The police eventually found him living in the city dump. He had apparently quit taking his medication and when he was discovered he was regressed and catatonic. He was readmitted to a state hospital.

By the early 1980s cases like Dave's had become commonplace in large cities throughout the nation. Vagrants and "bag ladies" appeared in abundance on city streets, and in transport terminals, flophouses, and the virtually always overwhelmed shelters for homeless persons hastily expanded in futile efforts to contain the tide of recently discharged patients. Street crime soared, as did the death rate among these hapless persons who were for the most part wholly lacking in survival resources for the harsh urban environment. As Westermeyer (1982a) noted:

> Patients are returned to the community, armed with drugs to control their illness. The worst aspects of their illnesses may be under control. But many of the patients are not ready to function in society. They need a gradual reintroduction—facilities where someone else can see that they take their drugs, see their psychiatrists, get food, clothing and shelter. Such care is too often more than families can provide and such services are not generally available in a community. As a result, the numbers of bag ladies and men, vagrants and mentally disabled people, living in lonely hotels and dangerous streets, have burgeoned. (p. 2)

The full extent of problems created by deinstitutionalization is not precisely known. The ambiguity comes, in part, from the scarcity of rigorous follow-up data on patients who have been discharged from mental hospitals. There have not been a sufficient number of adequate research studies in this area. Moreover, such research investigations have tended to be difficult to conduct because the patients are transient and are hard to keep track of over time.

Certainly not all homeless people are former mental patients, but evidence suggests that deinstitutionalization has contributed substantially to the number of homeless people (Jones, 1983; Lamb, 1984). Researchers have also demonstrated that a greater percentage of homeless people have significant psychopathology, as reflected in higher rates of hospitalization and felony convictions, than people who have homes (see Fischer et al., 1986). More recently, Rossi (1990) estimated that 33 percent of homeless individuals suffer from chronic mental disorder and about 33 percent have severe addiction problems.

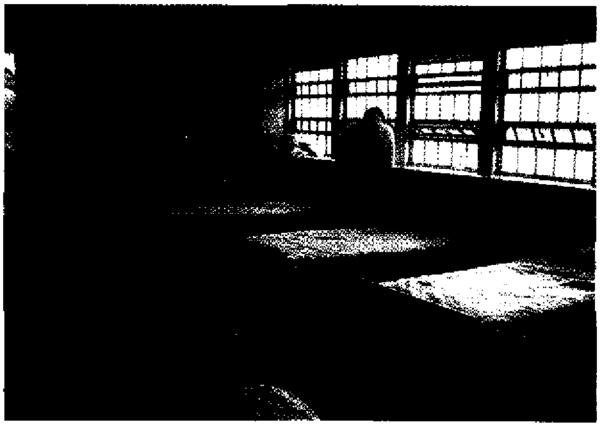
In spite of the problems just described, some data on patient discharge and outcome status support the deinstitutionalization process. Braun and colleagues (1981), for example, concluded:

> The most satisfactory studies allow the qualified conclusion that selected patients managed outside the hospital in experimental programs do no worse and by some criteria have psychiatric outcomes superior to those of hospitalized control patients. (p. 747)

These same researchers, however, also concluded that deinstitutionalization is likely to be unsuccessful if continuing care in the community is not available or if it is inadequate.

The various approaches that have been implemented to circumvent patient failures to readjust to the community have not been particularly successful at reducing hospital readmissions and therefore at further reducing the average daily census in state hospitals. Nevertheless, advocates for deinstitutionalization continue to maintain that this is the most desirable approach to treating the chronically mental ill. The controversy over deinstitutionalization is likely to continue over some time, with advocates on both sides of the issue, until more definitive research is conducted.

Meanwhile, the extent to which private (as opposed to publicly supported) mental health care, particularly private hospitalization, has expanded to fill at least part of the gap left by deinstitutionalization and inadequate funding for community mental health centers is not generally recognized. Deinstitutionalization notwithstanding, some 70 percent of all the dollars spent on mental health care are spent for hospitalization, much of it of the acute, short-term variety. These data, gathered by Kiesler and Simpkins (1993; Kiesler, 1993), indicate that the national investment in this relatively very costly type of approach is a huge one—in fact constituting an "unnoticed majority" of the total mental health intervention effort of the nation. Many of these inpatient stays, moreover, occur in nonspecialized (i.e., nonpsychiatric) units of general hospitals, a setting whose overall effectiveness in dealing with mental patients is questionable.



*The extent of problems created by deinstitutionalization is not fully known, but some evidence suggests that the emptying of mental hospitals has contributed to the number of homeless people. Deinstitutionalization is not likely to be successful unless continuing care is available and adequate in the community, and unless it allows for readmission to the hospital for short periods if necessary.*

Care in specialized, private mental hospitals or in specialized psychiatric units of private medical centers has long been an option for those families able to afford it—usually, until relatively recently, only wealthy ones. However, the mental health system appears to have undergone considerable evolution over time, due in large part to changes in funding for mental health care, with the result already noted. This phenomenon, referred to as the "privatization" of the mental health system (Dorwart et al., 1989), has developed primarily because private insurance companies have been persuaded to cover the cost of inpatient mental health services. Several large private hospital corporations have filled the treatment void left by the public mental hospital cutbacks and are providing inpatient psychiatric care for a substantial proportion of those patients currently receiving any type of formal treatment.

The result is that there has been *no* notable overall reduction in mental hospitalization in recent times (Kiesler, 1993). Rather, the demographics of the inpatient population has shifted in favor of a more socioeconomically advantaged group—that is, those who have medical insurance that contains provisions for psychiatric hospitalization. Because mental disorders are often chronic, this type of insurance tends to be very expensive (and hence aversive to employers), excluding many persons and families in less than affluent circumstances. With the continuing downsizing of public facilities, where do these people go? Some of them, as we have seen, go into the streets.

Another related development in the care of chronic mental patients is the growth and expansion of private nursing home facilities, particularly for the elderly mentally disordered. Since the deinstitutionalization movement spurred the discharge of psychiatric patients into the community, alternative care facilities have expanded to fill the need for continued care (Morlock, 1989). This expansion of facilities has been made possible through financial incentives provided by Medicare to fund treatment. Nursing homes have become the largest single setting to care for the chronic mentally ill. Mentally ill persons make up over 51 percent of the nursing home population at present (Goldman, Feder, & Scanlon, 1986).

As this is being written, the federal government is struggling with the problem of how to cope with the enormous costs involved in attempting to provide adequate and universal medical insurance coverage for all citizens. A huge part of the problem of needed health care reform is related to the escalating costs of hospitalization, felt by many to be out of control. It remains to be seen at this point whether the mental health sector will receive due consideration in whatever arrangements are finally enacted by the Congress. A factor of considerable importance here is the possibility that private hospitalization has come to be overutilized, relative to other less expensive but at least equally effective forms of intervention, in the mental health and substance abuse arenas (Kiesler, 1993; Kiesler & Simpkins, 1993; VandenBos, 1993). Plausible alternatives that do not involve inpatient care include enhanced preventive intervention and rehabilitative psychotherapy (VandenBos, 1993).

## ORGANIZED EFFORTS FOR MENTAL HEALTH

Public awareness of the magnitude and severity of our contemporary mental health problem and the interest of government, professional, and lay organizations have prompted programs directed at better understanding, more effective treatment, and long-range prevention. Efforts to improve mental health are apparent not only in our society, but also in many other countries; and international as well as national and local organizations and approaches are involved.

### U.S. Efforts for Mental Health

In the United States, the primary responsibility for dealing with mental disorders fell initially to state and local agencies. During World War II, however, the extent of mental disorders in the United States was brought to public attention when a large number of young men—two out of every seven recruits—were rejected for military service for psychiatric reasons. This discovery led to a variety of organized measures for coping with the nation's mental health problem.

**The Federal Government and Mental Health** In 1946, aware of the need for more research, training, and services in the field of mental health, Congress passed its first comprehensive mental health bill, the National Mental Health Act, which laid the basis for the federal government's programs in the 1950s and 1960s.

The 1946 bill provided for the establishment of a National Institute of Mental Health (NIMH) in or near Washington, D.C., to serve as a central research and training center and as headquarters for the administration of a grant-in-aid program. The grant-in-aid feature was designed to foster research and training elsewhere in the nation and to help state and local communities expand and improve their own mental health services. New powers were conferred on the NIMH in 1956, when Congress, under Title V of the Health Amendments Act, authorized the institute to provide "mental health project grants" for experimental studies, pilot projects, surveys, and general research having to do with the understanding, assessment, treatment, and aftercare of mental disorders. The present status of NIMH is that of a separate Institute under the National Institutes of Health, Public Health Service, U.S. Department of Health and Human Services.

The NIMH (a) conducts and supports research on the biological, psychosocial, and sociocultural aspects of mental disorders; (b) supports the training of professional and paraprofessional personnel in the mental health field; (c) assists communities in planning, establishing, and maintaining more effective mental health programs; and (d) provides information on mental health to the public and to the scientific community. Two companion institutes—the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the National Institute on

Drug Abuse (NIDA)—perform comparable functions in these more specialized fields.

Although the federal government provides leadership and financial aid, the states and localities actually plan and run most NIMH programs. In addition, the states establish, maintain, and supervise their own mental hospitals and clinics, leading to considerable variation among the states in the adequacy with which these responsibilities are met. A number of states have also pioneered, through their legislation, in the development of community mental health centers; rehabilitation services in the community for former patients; and facilities for dealing with alcoholism, drug abuse, and other special mental health problems. In the 1980s, federal support for mental health programs diminished considerably. Most state and local governments, which were expected to assume much of the support of mental health activities, have not been able to fund programs and facilities at 1960s and 1970s levels. As a result, many programs devoted to mental health training, research, and service have been greatly reduced or even abandoned. As to the future, there is, as already noted, considerable uncertainty about the extent to which problems of mental health will be included in forthcoming revisions of national health care policy, and about what forms any such inclusion might take.

**Professional Organizations and Mental Health** A number of national professional organizations exist in the mental health field. These include the American Psychological Association (APA), the American Psychological Society (APS), the American Psychiatric Association (APA), the American Medical Association (AMA), and the Association for the Advancement of Behavior Therapy (AABT).

One of the most important functions of these organizations is to set and maintain high professional and ethical standards within their special areas. This function may include (a) establishing and reviewing training qualifications for professional and paraprofessional personnel; (b) setting standards and procedures for the accreditation of undergraduate and graduate training programs; (c) setting standards for the accreditation of clinics, hospitals, or other service operations and carrying out inspections to see that the standards are followed; and (d) investigating reported cases of unethical or unprofessional conduct and taking disciplinary action when necessary.

A second key function of these professional organizations involves communication and information exchange within their areas via meetings, symposia, workshops, refresher courses, the publication of professional and scientific journals, and related activities. In addition, all such organizations sponsor programs of public education as a means of advancing the interests of their professions, drawing attention to mental health needs, and attracting students to careers in their areas.

A third key function of professional organizations, one that is receiving increasing attention, is the application of insights and methods to contemporary social problems—for example, in lobbying national and local government agencies to provide more services for homeless people. Professional mental health organizations are in a unique position to serve as consultants on mental health problems and programs.

**The Role of Voluntary Mental Health Organizations and Agencies** Although professional mental health personnel and organizations can give expert technical advice with regard to mental health needs and programs, real progress in helping plan and implement these programs must come from an informed and concerned citizenry. In fact, it has been repeatedly, and quite rightly, stated that it has been primarily concerned nonprofessionals who have blazed the trails in the mental health field.

Prominent among the many voluntary mental health agencies is the National Association for Mental Health (NAMH). This organization was founded in 1950 by the merger of the National Committee for Mental Hygiene, the National Mental Health Foundation, and the Psychiatric Foundation; it was further expanded in 1962 by merging with the National Organization for Mentally Ill Children. Through its national governing body and some 1000 local affiliates, the NAMH works for the improvement of services in community clinics and mental hospitals; it helps recruit, train, and place volunteers for service in treatment and aftercare programs; and it works for enlightened mental health legislation and for the provision of needed facilities and personnel. It also carries on special educational programs aimed at fostering positive mental health and helping people understand mental disorders. In addition, the National Association for Mental Health has been actively involved in many court decisions affecting patient rights (NAMH, 1979). In several cases the NAMH has sponsored litigation or served as *amicus curiae* (friend of the court) in efforts to establish the rights of mental patients to treatment, to freedom from custodial confinement, to freedom to live in the community, and to protection of their confidentiality.

With a program and organization similar to that of the NAMH, the National Association for Retarded Citizens (NARC) works to reduce the incidence of mental retardation, to seek community and residential treatment centers and services for the retarded, and to carry on a program of education aimed at better public understanding of retarded individuals and greater support for legislation on their behalf. The NARC also fosters scientific research into mental retardation, the recruitment and training of volunteer workers, and programs of community action.

These and other voluntary health organizations, such as Alcoholics Anonymous, need the backing of a wide constituency of knowledgeable and involved citizens in order to succeed.

### Mental Health Resources in Private Industry

Personal problems—such as marital distress or other family problems, alcohol or drug abuse, financial difficulties, or job-related stress—can adversely affect employee morale and performance. Psychological difficulties among employees may result in numerous problems, such as absenteeism, accident proneness, poor productivity, and high job turnover. The National Institute for Occupational Safety and Health (NIOSH) recognizes psychological disorders as one of the ten leading work-related health problems (Millar, 1990), and work-related mental health risk factors may be increasing with changes in the economy, in technology, and in demographic factors in the work force (Sauter, Murphy, & Hurrell, 1990).

While a great deal more research is needed in the identification of specific mental health risk factors in work situations, available knowledge (e.g., Sauter et al., 1990) suggests that serious unrecognized problems may exist in the following areas of job design and conditions of work.

1. *Work load and work pace.* The critical factor here appears to be the degree of *control* the worker may have over the pace of work rather than output demand per se. Machine-paced assembly work may be particularly hazardous to mental health.

2. *Work schedule.* Rotating "shifts" and night work have been associated with elevated risk for psychological difficulties.

3. *Role stressors.* Role ambiguity (e.g., who has responsibility for what?), said to be common in many work situations, has a negative impact on mental and physical health, as does role conflict (incompatible role demands).

4. *Career security factors.* Feelings of insecurity relating to issues such as job future or obsolescence, career development, and encouragement of early retirement adversely affect mental and physical health.

5. *Interpersonal relations.* Poor or unsupportive relationships among work colleagues significantly increase the risk for untoward psychological reactions.

6. *Job content.* Job dissatisfaction and poor mental health have been associated with work assignments involving fragmented, narrow, invariant tasks that allow for little creativity or sense of meaning with respect to contribution to the ultimate product.

Many corporations have long recognized the importance of worker mental health and of enhancing mental health–promoting factors in the workplace, and yet it has been a relatively recent phenomenon to see them act on this knowledge. Today many companies have expanded their "obligations" to employees to include numerous psychological services. Often referred to as employee-assistance programs (EAPs), these are the means through which larger corporations can actively provide mental health services to employees and their family members. In general, employers have been slower to deal with issues of job design and work environment as additional means of maximizing worker mental health. The latter would appear to be an area of expanding possibilities for the future (see Keita & Jones, 1990).

## International Efforts for Mental Health

Mental health is a major problem not only in the United States but of course in the rest of the world

*Employee-assistance programs are a relatively recent phenomenon that recognizes the link between psychological difficulties and job problems. Corporations are increasingly providing personal counseling and referral programs for employees having legal, financial, marital, and substance-abuse problems. Shown here is one such employee program that provides drug-rehabilitation telephone counseling.*

as well. Indeed, many of the unfavorable conditions in this country with regard to the causes and treatment of mental disorders are greatly magnified in poorer countries and countries with repressive governments. The severity of the world mental health problem is shown in the World Health Organization's estimates that mental disorders affect more than 200 million people worldwide. The recognition of this great problem served to bring about the formation of several international organizations at the end of World War II. We will briefly discuss here the World Health Organization (WHO) and the World Federation for Mental Health.

**The World Health Organization** The World Health Organization (WHO) has always been keenly aware of the close interrelationships between physical, psychosocial, and sociocultural factors—such as the influence of rapid change and social disruption on both physical and mental health; the impossibility of major progress toward mental health in societies where a large proportion of the population suffer from malnutrition, parasites, and disease; and the frequent psychological and cultural barriers to successful programs in family planning and public health.

Formed after World War II as part of the UN system, WHO's earliest focus was on physical diseases; through its efforts dramatic progress has been made toward the conquest of ancient scourges like smallpox and malaria. Over the years, mental health, too, became an increasing concern among the member countries. In response, WHO's present program now integrates mental health concerns with the broad problems of overall health and socioeconomic development that must be faced by member countries (WHO, 1978a).

WHO has headquarters in Geneva and regional offices for Africa, the Americas, Southeast Asia, Europe, the Eastern Mediterranean, and the Western Pacific. Hence its activities extend into areas with diverse physical environments, types of social organization, and mental health facilities. It enters a country only on invitation, helping identify the basic health needs of each country and working with the local authorities to plan and carry out the most useful and appropriate programs. Where possible, it strives to make its services available over a period of several years to ensure continuity and success for the programs that are undertaken.

Another important contribution of WHO has been its International Classification of Diseases, which enables clinicians and researchers in different countries to use a uniform set of diagnostic categories (WHO, 1978b). As we have seen, the American Psychiatric Association's DSM-IV classification has been coordinated with the WHO ICD-10 classification (Sartorius et al., 1993).

**The World Federation for Mental Health** The World Federation for Mental Health was established in 1948 as an international congress of nongovernmental organizations and individuals concerned with mental health. Its purpose is to promote international cooperation between governmental and nongovernmental mental health agencies, and its membership now extends to more than 50 countries. The federation has been granted consultative status by WHO and it assists the UN agencies by collecting information on mental health conditions all over the world.

We have now seen something of the maze of local, national, and international measures that are being undertaken in the mental health field. We can expect these efforts to continue. Furthermore, we can expect to see more and more mental health problems unraveled to reveal discoverable causes and to respond to treatment and prevention by scientific means. The 1990s have already witnessed an amazing openness and a diminishing of previously impassable borders. Along with this increased interchange of ideas and cooperation, we expect to see a broader interchange of mental health collaboration. Reductions in international tension and a greater international cooperation in the sciences and health planning will likely promote more sharing of information and views on mental health.

## CHALLENGES FOR THE FUTURE

The media confront us daily with the stark truth that we have a long way to go before our dreams of a better world are realized. Many question whether the United States or any other technologically advanced nation can achieve mental health for the majority of its citizens in our time. Racism, poverty, youth violence, the uprooting of third-world populations, and other social problems that contribute to mental disorder sometimes seem insurmountable.

Events in the rest of the world affect us also, both directly and indirectly. Worldwide economic instability and shortages and the possibility of the destruction of our planet's life support system breed widespread anxiety about the future. The vast resources we have spent on military programs over the past half-century to protect against perceived threats have absorbed funds and energy that otherwise might have been turned to meeting human and social needs here and elsewhere in the world. The limited resources we are now willing to apply to solving mental health problems prevent the solution of major problems resulting from drug and alcohol abuse, homelessness, broken families, and squalid living conditions for many.

## The Need for Planning

It seems imperative that more effective planning be done at community, national, and international levels if mental health problems are going to be reduced or eliminated. Many challenges must be met if we are to create a better world for ourselves and future generations. Without slackening our efforts to meet needs at home, we will probably find it increasingly essential to participate more broadly in international measures toward reducing group tensions and promoting mental health and a better world for people everywhere. At the same time, we can expect that measures undertaken to reduce international conflict and improve the general condition of humankind will make their contribution to our own nation's social progress and mental health. Both kinds of measures will require understanding and moral commitment from concerned citizens.

Within our own country, as well as the rest of the industrialized world, progress in lengthening the life span has brought with it burgeoning problems in the prevalence of disorders associated with advanced age, particularly in the area of dementing conditions such as Alzheimer's disease. As was noted in Chapter 13, there can be no assurance at this time that we will find the means of eradicating or arresting this threat before it has overwhelmed us in terms of the numbers of already living people affected. Planning and preparation would seem our only rational hope of forestalling a potential disaster of unprecedented yet predictable magnitude; we need to make a beginning.

## The Individual's Contribution

> *Each man can make a difference, and each man should try.*
>
> —John F. Kennedy

The history of abnormal psychology provides clear examples of individuals whose efforts were instrumental in changing thinking about problems. Recall that Pinel took off the chains, Dorothea Dix initiated a movement to improve the conditions of asylums, and Clifford Beers inspired the modern mental health movement with his autobiographical account of his own experience with mental illness. Who may lead the next revolution in mental health is anyone's guess. What is clear is that a great deal can be accomplished by individual effort.

When students become aware of the tremendous scope of the mental health problem both nationally and internationally and the woefully inadequate facilities for coping with it, they often ask, "What can I do?" Thus it seems appropriate to suggest a few of the lines of action interested students can profitably take.

Many opportunities in mental health work are open to trained personnel, both professional and paraprofessional. Social work, clinical psychology, psychiatry, and other mental health occupations are rewarding in terms of personal fulfillment. In addition, many occupations, ranging from law enforcement to teaching and the ministry, can and do play key roles in the mental health and well-being of many people. Training in all these fields usually offers individuals opportunities to work in community clinics and related facilities, to gain experience in understanding the needs and problems of people in distress, and to become familiar with community resources.

Citizens can find many ways to be of direct service if they are familiar with national and international resources and programs, and if they invest the effort necessary to learn about their community's special needs and problems. Whatever their roles in life—student, teacher, police officer, lawyer, homemaker, business executive, or trade unionist—their interests are directly at stake. For although the mental health of a nation may be manifested in many ways—in its purposes, courage, moral responsibility, scientific and cultural achievements, and quality of daily life—its health and resources derive ultimately from the individuals within it. In a participatory democracy, it is they who plan and implement the nation's goals.

Besides accepting some measure of responsibility for the mental health of others through the quality of one's own interpersonal relationships, there are several other constructive courses of action open to each citizen, including (a) serving as a volunteer in a mental hospital, community mental health center, or service organization; (b) supporting realistic measures for ensuring comprehensive health services for all age groups; and (c) working toward improved public education, responsible government, the alleviation of group prejudice, and the establishment of a more sane and harmonious world.

All of us are concerned with mental health for personal as well as altruistic reasons, for we want to overcome the harassing problems of contemporary living and find our share of happiness in a meaningful and fulfilling life. To do so, we may sometimes need the courage to admit that our problems are too much for us. When existence seems futile or the going becomes too difficult, it may help to remind ourselves of the following basic facts, which have been emphasized throughout this text: From time to time, each of us has serious difficulties in coping with the problems of living. During such crisis periods, we may need psychological and related assistance. Such difficulties are not a disgrace; they can happen to anyone if the stress is sufficiently severe. The early detection and correction of maladaptive behavior is of great importance in preventing the development of more severe or chronic conditions. Preventive measures—primary, secondary, and tertiary—are the most effective long-range approach to the solution of both individual and group mental health problems.

Recognizing these facts is essential because statistics show that almost all of us will at some time in our lives have to deal with severely maladaptive behavior or mental disorder either in ourselves or in someone close to us. Our interdependence and the loss to us all, individually and collectively, when any one of us fails to achieve his or her potential are eloquently expressed in the famous lines of John Donne (1624):

> No man is an island, entire of itself; every man is a piece of the continent, a part of the main. If a clod be washed away by the sea, Europe is less, as well as if a promontory were, as well as if a manor of thy friends or of thine own were: any man's death diminishes me, because I am involved in mankind, and therefore never send to know for whom the bell tolls; it tolls for thee.

## UNRESOLVED ISSUES

### on The Law–Mental Health Interface

In its "Introduction" the DSM-IV contains a "Cautionary Statement" that reads, in part:

> The purpose of DSM-IV is to provide clear descriptions of diagnostic categories in order to enable clinicians and investigators to diagnose, communicate about, study, and treat people with various mental disorders. It is to be understood that inclusion here, for clinical and research purposes, of a diagnostic category such as Pathological Gambling or Pedophilia does not imply that the condition meets legal or other nonmedical criteria for what constitutes mental disease, mental disorder, or mental disability. The clinical and scientific considerations involved in categorization of these conditions as mental disorders may not be wholly relevant to legal judgments, for example, that take into account such issues as individual responsibility, disability determination, and competency. (American Psychiatric Association, 1994, p. xxvii)

One might wish that such a statement, asserting (as we read it) the essential independence of professional diagnoses of mental disorder and questions that often go to the heart of issues in jurisprudence, would put an end to the endless and frequently baffling courtroom dramas in which (respectively competent and noncolluding) mental health expert witnesses and attorneys try—rarely with any great success—to achieve a common framework for communicating clearly between themselves and with judges and juries. Based on the problem's refractory history and on considerable collective experience as participants in such encounters, the authors doubt that the statement will have the intended effect—any more than did similar statements in DSM-IV's predecessors. If a disorder is "on the books," attorneys are very likely to attempt to make use of it, where feasible, in pursuit of their clients' interests; indeed, they may be ethically obliged to do so (see also the related "Unresolved Issues" section of Chapter 4, pp. 153–154).

As we see perhaps most clearly in the case of the insanity defense, the law tends to frame its issues relating to the mental states of parties to a trial in ways not ultimately resolvable by any scientifically reliable assessment methods known or available to mental health professionals. However, since no other definable group of potential experts has more, or even as much, likelihood of casting light into this darkness, the task usually defaults to psychiatrists and clinical psychologists. Since, unlike ordinary witnesses at trial, persons qualifying as experts are permitted to render "opinions," the way is open for the frequent and professionally embarrassing contradictions of expert testimony mentioned earlier in the chapter.

Though the insanity defense remains a major and relatively familiar unresolved issue at the law-mental health interface, it is by no means the only one. A large number of such problems hinge on questions of ***malingering***, deceitfully behaving in such a manner as to claim a mental or physical disorder or disability that one in fact does not have, normally in order to gain some legal advantage. The assessment of a defendant's competency to stand trial sometimes involves this issue, as indeed does the assessment of a convict's competency to be executed (some jurisdictions requiring that condemned persons be able to understand why they are being put to death). Again in this case, the mental health professional often becomes a principal witness, more or less by default.

Issues of this sort are also common in civil proceedings in which a person allegedly injured by the negligent behavior of another seeks financial compensation. The injury claimed by the plaintiff in such a suit is often one that proves difficult to document objectively and/or to be a readily understandable consequence of the causal event, for instance, a minor traffic "fender bender." Often complicating such cases is the question of ***unconscious*** malingering, sometimes referred to as "secondary gain," thought to be an element in many genuine instances of conversion disorder, a mental disorder recognized as such in the DSM (see Chapter 7). While certain observations and assessment procedures available to trained mental health practitioners may well tilt the probabilities in one direction or the other, findings approaching reasonable certainty (in the scientific, rather than the legal, meaning of this term) about malingering or its absence are normally unattainable in situations of this sort. Training and experience in a mental health discipline does not confer the ability to read minds.

Possibly the most bizarrely fascinating of the unresolved issues at the law-mental health interface are those raised by the phenomenon of multiple personality disorder, now called ***dissociative identity disorder*** (DID), which as we saw in Chapter 7 has become a somewhat common diagnosis in recent years. Although some professionals dispute even the existence of such a condition, its controversial nature is not a compelling consideration in the legal context. It appears in the DSM-IV (as it did in all of DSM-IV's predecessors), and despite the disclaimer quoted at the beginning of this discussion, that makes it a genuine clinical entity within the legal community, as already noted.

The general nature of the problem can be stated quite succinctly: Within a legal system strongly oriented to the precise identification of ***individual*** responsibility for acts, what if any are the limits of the assignment of responsibility and sanctions for infractions of the law where the same physical space and body are occupied at different times by more than one distinct and legally recognizable person? The magnitude of the potential legal havoc involved here might best be captured in a listing of only ***some*** of the problems already encountered or certain to be encountered in due course:

- Who, among various co-personalities, is empowered to sign for withdrawals from a bank account?
- Are the provisions and obligations of a contract entered into by one constituent personality binding to all others, regardless of their particular desires in the matter?
- Does the swearing of an oath, as in court, apply to the entire collection of personalities, or must each be sworn individually if he or she is to testify?
- In the case of a guilty verdict for the criminal act of a given personality, where other personalities did not acquiesce in the crime, how should punishment be fairly meted out?
- If no constituent personality meets a test of insanity, is it reasonable and lawful to declare DID itself an instance of insanity?
- Has rape occurred where the co-personalities of a 26-year-old woman who had acquiesced to intercourse vehemently objected to its occurrence (as in a case that was actually prosecuted in Wisconsin in 1990)?
- And, of course, the most common real-life legal dilemma: Should an individual, as the primary personality, be held legally accountable for, say, a capital crime that evidence suggests may have actually been committed surreptitiously, so to speak, by an alter personality?

The scenario just mentioned has rather often been the contention underlying a plea of "not guilty by reason of insanity" (NGRI). Usually, as in the case of the Hillside Strangler Kenneth Bianchi (convicted of 12 rapes and murders in California and Washington State), it has failed. On a very few occasions, however, the NGRI plea in association with a claim that the actual criminal was a DID alter has worked, as in the well-publicized 1978 case of Ohio resident Billy Milligan, claiming to be host to ten personalities and accused of raping four women (*New York Times*, May 9, 1994).

The legal conundrums inspired by the DID construct admittedly have a quality of whimsy about them, perhaps especially for persons not trained in the sometimes arcane ways of the law. It would be well to remind ourselves, therefore, that the problems encountered here are often serious ones—sometimes, indeed, ***deadly*** serious.

A fundamental function of the law is that of providing an instrument for the unbiased, just, and peaceful resolution of disputable conflicts of interest among human beings and between human beings and their societies. As such, the law functions as a kind of final arbiter in situations that are commonly among the most convoluted and perplexing in human experience, and it is often called upon to render its judgments in the absence of pertinent but unobtainable knowledge. As we have seen, many of the issues it deems critical are concerned with the private states of mind of its subjects, a difficult challenge that is shared by the scientists and professionals of the mental health disciplines. This common challenge would seem to call for high levels of collaboration and mutual inquiry between scholars in the two domains, but such cooperative ventures have in fact been historically rare. Perhaps it is time to seek means of overcoming that traditional isolation.

## SUMMARY

Increasingly today, professionals are trying not only to cure mental health problems but also to prevent them, or at least reduce their effects. Prevention can be viewed as focusing on three levels. Primary prevention is aimed at reducing the possibility of disorder and fostering positive mental health efforts. Secondary prevention attempts to reduce the impact or duration of a problem that has already occurred. Tertiary prevention attempts to reduce the long-term consequences of having had a disorder.

In recent years, several legal issues concerning the treatment of mental patients have surfaced. The commitment process and procedures for committing individuals for inpatient care have been reconsidered. Being "mentally ill" is not considered sufficient grounds for commitment. There must be, in addition, evidence that the individual is either dangerous to himself or herself or represents a danger to society. It is not an easy matter, even for trained professionals, to determine in advance if a person is "dangerous" and likely to cause harm to others. Nevertheless, professionals must, at times, make such judgments. Recent court rulings have found professionals liable when patients they were treating caused harm to others. The *Tarasoff II* decision held that a therapist has a duty to protect potential victims if his or her patient has threatened to kill them.

Another important issue of forensic psychology involves the insanity plea for capital crimes. Many mental health and legal professionals, journalists, and laypersons have questioned the present use of the "not guilty by reason of insanity" (NGRI) defense. The original legal precedent, the M'Naughten Rule, held that, at the time of committing the act, the accused must have been laboring under such a defect of reason as to not know the nature and quality of the act or to not know that what he or she was doing was wrong. More recent broadenings of the insanity plea, as in the American Law Institute standard, leave open the possibility of valid NGRI pleas by persons who are not diagnosed to be psychotic. This broadening of the insanity plea led to its use in more and more cases, and decisions have often involved conflicting psychiatric testimony. The successful use of the NGRI defense by John Hinckley, attempted assassin of President Reagan, set off a storm of protest, resulting ultimately in widespread tightening of insanity defense laws. One effective and widely adopted reform was to shift the burden of proof to the defense in such cases.

There has been a great deal of legal controversy recently over the release of patients from public mental hospitals, called deinstitutionalization, and the failure to provide adequate follow-up of these patients in the community. In their zeal to close large psychiatric institutions, many administrators underestimated the amount of care that would be needed after discharge, and overestimated communities' abilities to deal with patients with chronic problems. The result was that some chronic patients were placed in circumstances that required more adaptive abilities than they possessed. Recent work in the area of aftercare for former mental patients has provided clearer guidelines for discharge and therapeutic follow-up. Meanwhile, there has been a burgeoning use of private hospitalization in psychiatric care, an expensive alternative not normally available to the less than affluent.

A large number of organizations are concerned and involved with establishing organized efforts for mental health. Several government agencies have mental health as their primary mission. For example, federal agencies such as the National Institute of Mental Health (NIMH), the National Institute on Drug Abuse (NIDA), and the National Institute on Alcohol Abuse and Alcoholism (NIAAA) are devoted to promoting varied research, training, and service. State and county government agencies may focus their efforts on the delivery of mental health services to residents on an inpatient or outpatient basis.

Mental health programming in the United States is also the concern of several professional and mental health organizations, many corporations, and a number of voluntary mental health organizations. In addition, international organizations, such as the World Health Organization (WHO) and the World Federation for Mental Health, have contributed to mental health programs worldwide.

Multiple unresolved issues continue to exist at the interface of the legal and mental health professions, indicating the desirability of increased collaboration between them.

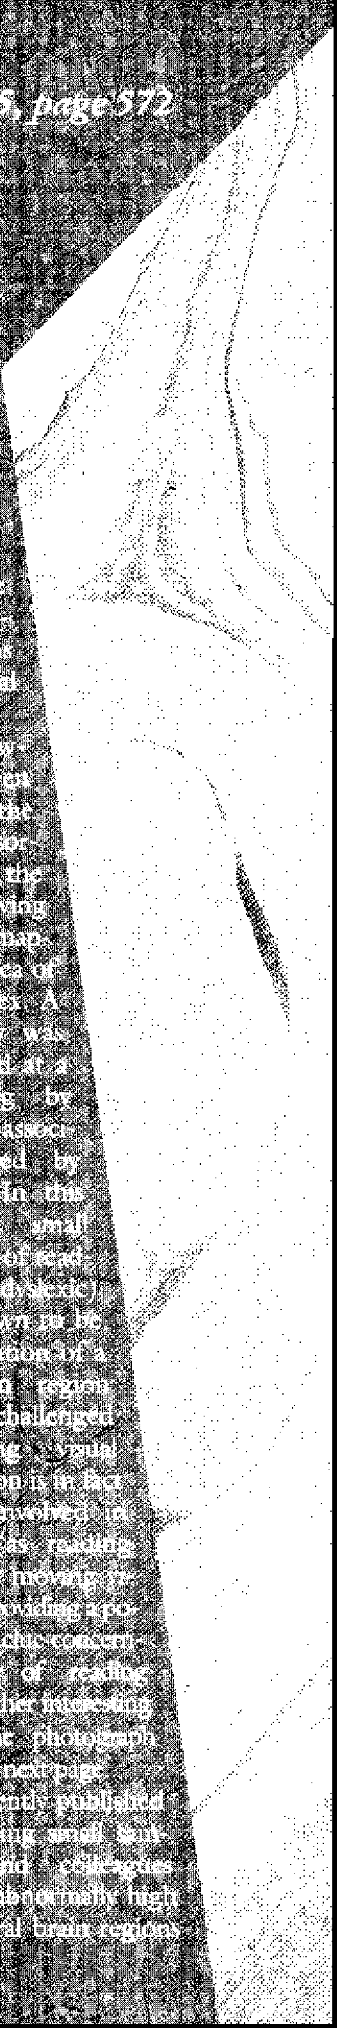
# CUTTING EDGE 6

# FUNCTIONAL MAGNETIC RESONANCE IMAGING



Magnetic resonance imaging (MRI) has increasingly replaced computerized axial tomography (CAT) as the technique of choice in detecting structural (anatomical) anomalies in the central nervous system, particularly the brain. The images of the interior of the brain are frequently sharper with MRI than with CAT because of the former's superior ability to differentiate subtle variations in soft tissue. In addition, the MRI procedure is normally far less complicated to administer, and it does not (like CAT) subject the patient to ionizing radiation. In fact, the major problem encountered with MRI is that some patients have a claustrophobic reaction to being placed into the narrow cylinder of the MRI machine, necessitated for containing the magnetic field and blocking out external radio signals.

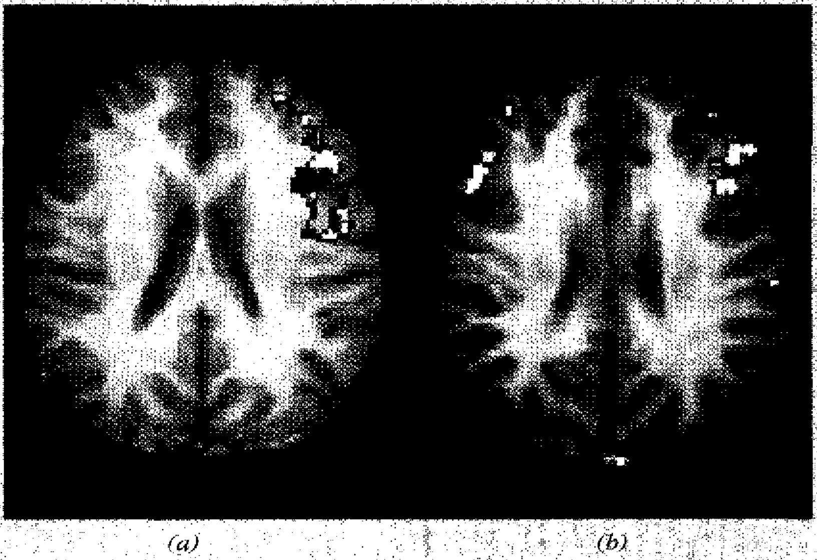
When Chapter 15 was written, the technique known as *functional MRI* (fMRI) had only recently been developed and had not yet been applied in the study of psychopathology. The main purpose of this addendum is to update rapidly progressing developments in this area.

As originally developed and employed, MRI could reveal brain *structure* but not brain *activity*. For the latter, clinicians and investigators remained dependent on positron emission tomography (PET) scans, whose principal shortcoming is the very expensive requirement of having a cyclotron nearby to produce the short-lived radioactive atoms needed to carry out the procedure. Because of this expense, the number of available centers in the United States equipped to do PET scans is estimated to be fewer than 100. The required introduction of radioactive substances, albeit short-lived ones, into the patient's body is also worrisome to many clinicians. It was apparent by the mid-1980s that adapting the MRI technique would be of tremendous advantage in revealing the workings of the brain as well as its anatomy, hence functional MRI. This breakthrough, considered by many to be the most revolutionary of all the imaging techniques, was accomplished in the early 1990s (*Harvard Mental Health Letter, 13*(7), January, 1997).

The specific mechanisms underlying fMRI assessment (not to mention those involved in MRI itself) are too technical to be reviewed in detail here. Simply put, in its most common form fMRI measures changes in local oxygenation (i.e., blood flow) of specific areas of brain tissue that in turn depend on neuronal activity in those specific regions. Ongoing psychological activity, such as sensations, images, and thoughts, can thus be "mapped," at least in principle, revealing the specific areas of the brain that appear to be involved in their neurophysiological mediation. Because the measurement of change in this context is critically time dependent, the emergence of fMRI required the development of high-speed devices for enhancing the recording process as well as the computerized analysis of incoming data. These improvements are now widely available and will doubtless lead to a marked increase in studies of disordered persons using functional imaging.

To date, however, little has been published in the area of mental disorder, most of the work thus far having concentrated on mapping the visual area of the cerebral cortex. A transitional study was recently presented at a national meeting by Paula Tallal and associates (as reported by Travis, 1996a). In this work, involving small samples, a group of reading-disordered (dyslexic) children was shown to be deficient in activation of a grape-sized brain region called V5 when challenged with fast-moving visual stimuli. This region is in fact believed to be involved in the processing (as reading entails) of rapidly moving visual stimuli, thus providing a potentially important clue concerning the origins of reading disorders. For another interesting technique, see the photograph and caption on the next page.

In another recently published study, also involving small samples, Breiter and colleagues (1996) reported abnormally high activation in several brain regions



In a study of 19 men and 19 women, researchers recently reported the first direct evidence that male and female brains tend to function differently during a specific task (Shaywitz et al., 1995). In these fMRIs, the orientation is as if from below the brain, so the left hemisphere is on the right and vice versa. During the first step in the process of sounding out words, Broca's area, the small left-hemisphere area associated with speech, was active in the men's brains (a). Eight women also had this pattern, but the brains of the other 11 showed activity on both sides (b). The two sexes performed equally well on the task, leading the researchers to conclude that nature has efficiently provided the brain with different routes to the same ability. However, the results might help explain why left-hemisphere damage is less likely to cause language problems in women than men following a stroke.

among obsessive–compulsive subjects when they were challenged with simulated "provocative" stimuli, for example, for a patient preoccupied with contamination, holding a towel "dipped in toilet water." Unfortunately, a good deal of data were rendered unusable because of subject movement while in the MRI apparatus, a condition that may indicate a problem with the use of the technique in psychiatric populations. Even minimal head movement during critical phases of the examination precludes obtaining an adequate fMRI (or MRI) recording. Many mentally disordered patients are highly tense and agitated, particularly when challenged with stressors. In addition, many of the tasks mental health researchers might wish to employ in such assessments (e.g., approach to or avoidance of phobic stimuli) are not physically possible if the patient cannot move his or her head. This last problem, at least, may at times be circumvented with the use of yet another marvel of contemporary technology, that is, virtual reality. Geoffrey Aguirre and his associates at the University of Pennsylvania (as reported by Travis, 1996b) have begun experimenting, apparently successfully, with the creation of virtual environments that allow immobilized fMRI subjects to engage a simulated but compelling environment.

Several investigators have recently become involved in the use of fMRI to try to pinpoint areas of aberrant brain functioning in schizophrenia, as reported by McCarley, Hsiao, Freedman, Pfefferbaum, and Donchin (1996). Cohen and Green (1995), for example, have reported an association between the occurrence of auditory hallucinations among persons diagnosed as schizophrenic and activation of brain centers believed to be involved in the reception of speech.

Given the unique advantages of fMRI brain imaging, mental health researchers will continue to find ways to cope with the relatively minor problems it poses for often distraught psychiatric patients. The scientific future of the approach thus appears ensured.

# CUTTING EDGE 7

# NEW DEVELOPMENTS IN THE TREATMENT OF DEPRESSION

Pharmacological researchers continue to develop medications for the treatment of mental disorders, thus serving to expand the range of clinical treatment options. Much effort is currently focused on developing safer medications with less troublesome side effects. The federal agency responsible for monitoring the safety of medication, the Food and Drug Administration, has recently approved several new treatments for depression. Two new drugs, nefazodone and venlafaxine, which have shown early promise in reducing depression effectively with fewer problematic side effects, are likely to be used widely in pharmacological therapy in the future.

## NEFAZODONE (SERZONE)

Nefazodone is an orally administered antidepressant with a chemical structure related to that of phenylpiperazine (Desyrel) and is rather dissimilar in chemical structure and operation to the SSRIs, which are widely used antidepressants (*Medical Letter*, 1995; *Physician's Desk Reference*, 1997a). Nefazodone is believed to work by blocking postsynaptic serotonin absorption, in contrast to the SSRIs which operate to block serotonin reuptake into the presynaptic neuron. Nefazodone has been found to differ from other antidepressants in producing fewer unwanted side effects, such as sexual dysfunction and sleeping disorders.

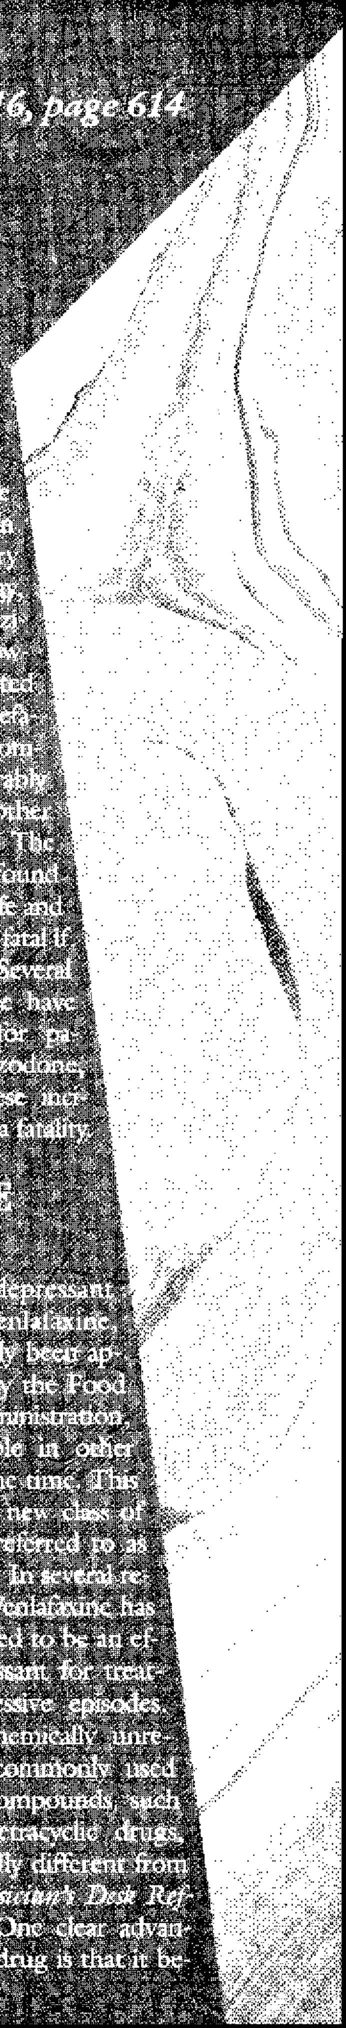
A period of clinical trials with nefazodone has been successfully completed, and the drug has been found to be effective in treating a broad range of depressive disorders, including dysthymia, major depression, and even some cases of bipolar disorder. Nefazodone has been shown to be as effective as imipramine in reducing major depression (Rickels et al., 1994). Some caution has been recommended, however, when the drug is given to bipolar patients who are not currently being treated with a mood-regulating medication such as lithium. This medication, like many antidepressants, can trigger manic episodes in bipolar patients. An additional consideration for prescribing nefazodone is that it can interact negatively with other medications. For example, the use of nefazodone with antianxiety compounds such as alprazolam (Xanax) or triazolam (Halcion) or with antihistamine medication such as terfenadine (Seldane) could prove life-threatening. Caution has also been suggested in prescribing nefazodone to persons who have liver disease. The clinical trials indicated that such persons should receive reduced dosages of nefazodone.

The antidepressant effect associated with nefazodone is usually experienced within two to three weeks after the patient begins to take the medication, somewhat earlier than other medications, such as amitriptyline (Elavil). One important finding from the preliminary trials is that nefazodone appears to work in a similar manner in elderly patients and younger patients, although at a lower dosage. This medication therefore might prove to be an effective alternative treatment for older patients for whom biochemical therapy for depression is often problematic.

Although nefazodone is considered to be a relatively problem-free drug, some side effects have been reported: dry mouth, lethargy, nausea, and dizziness. Overall, however, the reported side effects of nefazodone have compared very favorably with those of other antidepressants. The drug has been found to be relatively safe and is not likely to be fatal if taken in excess. Several cases of overdose have been reported for patients taking nefazodone, but none of these incidents resulted in a fatality.

## VENLAFAXINE (EFFEXOR)

Another antidepressant medication, venlafaxine, which has recently been approved for use by the Food and Drug Administration, has been available in other countries for some time. This drug is one of a new class of antidepressants, referred to as phenethylamines. In several recent drug trials Venlafaxine has been demonstrated to be an effective antidepressant for treating major depressive episodes. Venlafaxine is chemically unrelated to other commonly used antidepressant compounds, such as tricyclic or tetracyclic drugs, and it is chemically different from nefazodone (*Physician's Desk Reference*, 1997b). One clear advantage of this new drug is that it be-



gins to operate much faster than other antidepressants—in about two weeks—and may provide earlier relief for depressed patients.

The clinical effectiveness of venlafaxine has been established through controlled clinical trials. The drug appears to work best on major depressive disorder, reducing the affective disorder symptoms as effectively as other antidepressants. There are clear contraindications for using venlafaxine, however. First, patients who are taking monoamine oxidase inhibitors (MAOI) should not take venlafaxine because the combination of these medications is life-threatening. Thus, when an antidepressant medication is changed, a period of 14 days is required for the effects of the initial medication to wear off before the new drug is initiated. Second, insufficient information exists on the use of venlafaxine in patients with heart disease. Several potential side effects also have been found with venlafaxine, including increases in blood pressure. Therefore, one important contraindication to the use of venlafaxine is hypertension. Some patients also reported experiencing an increase in symptoms of anxiety when they used the drug. These unwanted psychological concomitants might be problematic for some patients.

Another potentially troublesome problem connected with venlafaxine is possible changes in appetite and weight. Anorexia and weight loss were reported in a significant percentage of patients in the clinical trials. In cases in which weight loss could be problematic for the patient, venlafaxine may not be the drug of choice.

The two newly approved antidepressants, nefazodone and venlafaxine, show a great deal of promise for reducing symptoms of depression in a broad range of patients. Moreover, early trials suggest that they are both relatively safe medications, that is, drug overdose (a frequent problem in pharmacological therapy with depressed patients) is a less threatening consequence than with other medications. Finally, both drugs have been shown to have fewer adverse side effects than other antidepressant medications.

In spite of all this attention and interest in developing new and safer medications for depression, recent evidence questions whether medications are actually the preferred treatment—especially as the medical community has claimed them to be for severe depression. As discussed more extensively in Chapter 17, one very large NIMH collaborative study (Elkin et al., 1989) for the treatment of depression concluded that medications were superior to cognitive therapy in the treatment of severe depression, and recent medical guidelines have been based on the results of that one study. DeRubeis (1997), however, has challenged this conclusion in a quantitative review of the literature. Collapsing the results of four very similar studies, DeRubeis finds that cognitive therapy is as effective as medication in the treatment of severe depression. He notes that only one study (the NIMH collaborative study), which accounts for only a third of the relevant results, found medications to be superior to cognitive therapy.

Moreover, this was not because medications did more poorly in the other three studies, but rather because cognitive therapy did more poorly in the NIMH study—and then only at two of the three study sites. Finally, the other three studies actually showed a slight advantage to cognitive therapy over medication (DeRubeis, 1997).

That the effectiveness of cognitive therapy may differ more across studies than does the effectiveness of medications is not surprising given that administration of medications is fairly standard across sites, whereas the administration of cognitive therapy requires specialized training in its techniques and not every cognitive therapist may show comparable expertise (DeRubeis, 1997). Although one could use this as an argument for medications being more practical, there are good reasons not to draw this conclusion. Specifically, there are strong suggestions from several of these studies that cognitive therapy provides protection against relapse (a big problem in the treatment of depression discussed in Chapter 6) that is not provided by medication. At a minimum medical treatment guidelines should be more careful to note the advantages and disadvantages of pharmacotherapy so that consumers (depressed patients and their relatives) can make more informed choices about which type of treatment to try. Persons, Thase, and Crits-Cristoph (1996) reached a very similar conclusion in a more qualitative review of the research literature in which they criticized current medical guidelines on very similar grounds.

# CUTTING EDGE 8

# A RAY OF HOPE IN PREVENTING ALCOHOL AND OTHER DRUG PROBLEMS

Prominent social forces such as attractive advertising, the influence of peer groups, negative parental role models, and the ready availability of many drugs are instrumental in promoting the early use of alcohol, tobacco, and illegal drugs in young people. Because these factors influence adolescents to begin using alcohol and drugs, it might appear reasonable to think that if these forces could be counterbalanced with equally powerful alternative influences, substance use might be delayed or even blocked altogether. This is easier said than done, and social efforts to alleviate the substance abuse problem have proved insufficient. Recent years have witnessed a sharp increase in marijuana, alcohol, and tobacco use among adolescents (Johnston, O'Mally, & Bachman, 1995). The extent and often dramatic impact of alcohol and drug use among adolescents are alarming, particularly that for binge drinking (National Institute on Drug Abuse, 1996). A recent survey found that 55% of 8th graders, 71% of 10th graders, 81% of 12th graders, and 90% of college students have tried alcohol. Heavy drinking, defined as five or more drinks in a row, has shown an alarming rate of incidence (15% for 8th graders, 24% for 10th graders, 30% for 12th graders, and 40% for college students). Heavy alcohol use among young people can lead to tragic consequences such as motor vehicle accidents involving emergency room admissions (National Clearinghouse for Alcohol and Drug Information, 1996) or in which several young people die as a result of drinking and driving (National Highway Traffic Safety Administration, 1990).

The federal government has approached the drug abuse problem with three broad strategies:

1. *Interfering with and reducing the supply of drugs available.* Policing our borders to intercept shipments of drugs has had little impact on their availability. The supply of illegal drugs seems to be endless. Even when drug agents know a shipment of illegal drugs is bound for the United States from suppliers in South America, they are often unable to stop it. Moreover, drug interception programs do little to affect the supply of alcohol and tobacco—the two drugs most abused by adolescents. These drugs are, of course, available in corner stores and even in the adolescent's home. Reducing the supply of these drugs to adolescents is extremely difficult.
2. *Providing treatment services for those who develop drug problems.* Although much money is spent each year on amelioration efforts, the treatment of substance abuse is perhaps the least effective avenue to reducing the problem. Addictive disorders are very intractable, and treatment failures are the rule rather than the exception. Therapeutic programs for those addicted to drugs or alcohol, though necessary, are not the answer to eliminating or even reducing the problems in our society.
3. *Encouraging prevention.* By far the most desirable and potentially most powerful means of reducing the drug problem in our country is through prevention methods aimed at alerting citizens to the problems of drugs and teaching young people ways to avoid using them (Botvin & Botvin, 1992; Botvin et al., 1995). Several past efforts have had limited success in resolving the adolescent drug abuse crisis. As noted in the text, the lackluster performance of prevention programs has provided little reason for optimism. Initially promising prevention efforts have often failed to show the desired reduction in substance use for a number of reasons. The intervention typically has not been conducted long enough to show the desired effect; the intervention efforts have not

been powerful enough to make a sufficient impact on the participants; or the intervention may not have been well implemented.

Two recent publications developed through comprehensive longitudinal prevention programs provide reason for optimism. Project Northland, developed by Perry and colleagues (1996) is a broad-based, action-oriented prevention program that involves many facets of the community to delay the onset of drinking in young teenagers. The community intervention approach followed by Project Northland researchers incorporates a number of elements to support a strong "no use" message during early adolescence. This project was initiated with great care to eliminate past methodological woes and provide a sound, comprehensive intervention philosophy.

The goals of Project Northland are to prevent or reduce alcohol use among adolescents by using a multilevel, community-based approach. The investigators conducted their program in 24 school districts in communities in northern Minnesota, an area that has been notorious for high rates of alcohol abuse in the past. The intervention included implementing a social-behavioral curriculum in the schools (beginning at the sixth grade), incorporating parent education programs, enlisting and involving peer leadership, and developing community-wide activities to alter the messages that young people typically receive about alcohol. Assessments were made annually to measure the use of alcohol among both the identified target population and the control samples. The program encompasses a set of four activity booklets for students to complete as homework assignments with their parents over a period of four weeks. Each booklet has activities that contain explicit behavioral objectives (e.g., how to establish family rules about drinking). Elected peer leaders provide activity tasks each week, with the assistance of their teachers. These sessions are conducted in small groups. Intensive teacher training sessions are provided before the intervention program begins, as well as peer-leader training. During the intervention phase of the program each child is asked to return score cards (signed by parents to record participation) on a prominently displayed scoreboard. Students receive prizes for completion of the first two booklets (e.g., a pen) and a T-shirt at the end of the program. The program ends with an event at each school that brings fifth-graders and their parents together for an evening event. During the week before the event, students work together in pairs on poster projects with alcohol-related messages that are presented to parents during the evening event.

Project Northland staff have been able to maintain broad participation in the program over three years and have shown that multilevel, targeted prevention programs for young adolescents are effective in reducing their alcohol use. Significantly lower rates (21% less) of alcohol use, cigarette smoking, and marijuana use were reported by adolescents in the intervention schools than by those in the reference schools, most of whom reserved the DARE program.

Another extensive and comprehensive drug prevention program with even more impressive results was recently completed by Botvin and his colleagues (Botvin et al., 1995). This five-year program involved 3597 adolescents in 56 public schools, who were followed up for five years beginning in the seventh grade. The initial intervention consisted of 15 classes, ten booster sessions in the eighth grade, and five booster sessions in the ninth grade. The adolescents were taught specific drug-resistance skills and general life skills in a classroom-based program. Like the Northland Project, this study found that drug abuse prevention programs conducted during junior high school "can produce meaningful and durable reductions" in tobacco, alcohol, and marijuana use if they teach social resistance skills and general life skills. Significant reductions in substance use were reported for the experimental schools compared with the control schools. There were 44% fewer drug users and 66% fewer polydrug users (tobacco, marijuana, and alcohol) in the prevention group. It was found, however, that "booster" sessions were necessary for the effect to be maintained.

These projects have clearly shown an effective path toward reducing the extent of substance abuse in young people. Carefully implemented educational programs along with teaching young people the skills needed to resist demands to begin using alcohol and drugs are powerful interventions. Armed with appropriate information and having practice at resisting others around them, adolescents can be successful in avoiding alcohol or drug use. The visible success of these programs has come to the attention of educators in other school districts, and a number of efforts are under way to "export" these laboratory programs for broader use elsewhere in America.

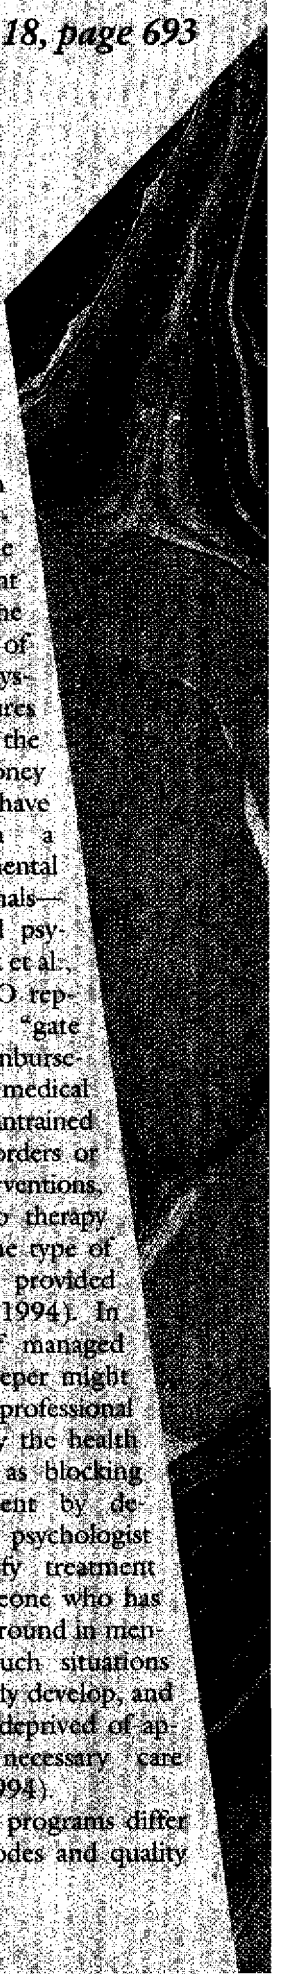
# CUTTING EDGE 9

# THE CRISIS IN MENTAL HEALTH CARE



Health care costs are reportedly rising more rapidly than any other aspect of the American economy (Resnick & DeLeon, 1995). O'Conner (1996) pointed out that some businesses spent as much on health care as their employees earned. Over the past decade, health care costs have skyrocketed as the number of people receiving services has increased over 30% per year (Giles, 1993). About one out of every three Americans experience psychological problems that could qualify them for a psychiatric diagnosis (Regier et. al., 1988), and about one in five of these receives mental health treatment (Castro, 1993). It has recently been estimated that psychiatric treatment accounts for about one-quarter of all hospital days in America (Kiesler & Sibulkin, 1987).

In response to these needs, health care administrators have created a diverse array of programs in an attempt to provide services at a cost that society can afford. *Managed health care* refers to a system of corporations that secure services from hospitals, physicians, and other health care providers for a designated population (Resnick et al., 1994). Managed health care providers attempt to offer services at lower costs by limiting traditional services, using stringent review procedures, and using lower-cost brief treatment options (Glazer & Gray, 1996). These systems operate by marketing health care plans to employers or individuals. For a fixed prepaid fee, employers and individuals subscribe to a health service company or an HMO (health maintenance organization), which entitles them to the services provided by that health plan (Resnick et al., 1994). These programs establish a treatment staff through a system of professionals, referred to as "panels," who are considered to be effective and efficient in providing a wide range of services (Cummings, 1995). Some HMOs (referred to as open-panel systems) allow patients some choice of health providers and allow any qualified professional in the community to participate. Most systems, however, are of the close-panel type, which limit the selection of available providers. Benefits vary from plan to plan and usually include limits on the problems covered or the maximum amount of care provided or services available. To keep costs low, some HMOs operate according to a system of "capitation," a method of payment in which a health provider contracts to deliver all the health care services required by a population for a fixed cost or flat fee per enrolled member or employee (Richardson & Austad, 1994). The HMOs assume some risk, but capitation allows for great profit if the subscriber's fees can be set higher than the cost of providing health services.

In one common approach to reducing health care costs, the managed care agency negotiates a reduced price directly with the provider. The provider then bills the health service organization for the time spent, and the HMO can obtain "low bid" services from the health professional (Richardson & Austad, 1994). This approach poses little financial risk to the provider. As might be apparent to the casual observer of managed care systems, the procedures for determining the amount of money paid to providers have frequently been a problem for mental health professionals—psychologists and psychiatrists (Resnick et al., 1994). The HMO representative, or "gate keeper" to reimbursement, often a medical generalist who is untrained in psychiatric disorders or psychosocial interventions, controls access to therapy and sometimes the type of treatment to be provided (Resnick et al., 1994). In some systems of managed care, the gate keeper might be a business professional who is viewed by the health service provider as blocking adequate treatment by demanding that the psychologist periodically justify treatment decisions to someone who has little or no background in mental health. In such situations conflicts frequently develop, and patients may be deprived of appropriate and necessary care (Resnick et al., 1994).

Managed care programs differ widely in the modes and quality of mental health services provided. Although their stated intention is to provide the most effective treatments available, decisions about what treatments to provide are often based more on business factors than on treatment considerations. HMOs that are overly cost conscious have come to be viewed by many in the field as simply tending to business to the neglect of the patient's needs (Karon, 1995; Hoyt & Austad, 1992; Schreter, Sharfstein, & Schreter, 1994).

The mental health services typically covered by HMOs include less expensive and less labor-intensive approaches. As might be expected, pharmacotherapy is the most frequent mental health treatment provided by HMOs. Some managed health care systems have advocated the use of somatic therapies in an attempt to contain costs. Gibson (1994) pointed out, for example, that Federal Employees Blue Cross reviewers once followed a set of guidelines promoting the use of radical medical procedures (psychosurgery, insulin therapy, high-dosage drug therapy, and ECT) over psychosocial interventions and low-dosage pharmacotherapy. Psychosocial interventions such as individual psychotherapy are discouraged or limited to relatively few sessions. Lazarus (1996) pointed out that long-term psychotherapy has been virtually eliminated for all but a small number of wealthy private clients. On the other hand, group psychotherapy is often promoted and encouraged because it gives the appearance of being cost effective.

Most managed care corporations have adopted the model of providing focused, brief, intermittent mental health treatment (Cummings, 1995; Hoyt & Austad, 1992) for most problems. Patients who require longer treatments or need inpatient hospitalization are typically not well served in managed care organizations (Gabbard, 1994). In fact, long-term mental health treatment is typically discouraged by managed health care organizations. For example, most managed care groups approve only short inpatient stays (less than ten days) and four to six sessions of outpatient mental health treatment at a time.

Although a great deal of energy has been invested in resolving society's health care delivery problems, there is little evidence that these efforts have either served to slow the increasing costs of mental health care or have enabled professionals to better meet mental health treatment needs.

The ultimate success of managed mental health care programs depends on their ability to control both access to treatment and quality of services. Interestingly, few if any of the decisions regarding the amount and type of services provided are guided directly by empirical criteria. Decisions of whether to cover 8 versus 20 sessions of psychotherapy, for example, are arbitrary and often seem capricious both to the practitioner and to the patient (Harwood et al., in press). Harwood and colleagues have pointed out that service decisions often rest on uncertain assumptions. They concluded that there are no consistently accepted criteria for selecting among psychosocial interventions, or for that matter, for determining when to provide various combinations of psychosocial and medical treatments.

A clear rift has developed between service providers and managers. Available services are often governed more by financial concerns than by a mental health professional's judgment. Practitioners, as a result, are expressing outrage over the situation. O'Conner (1996) referred to this reaction by the mental health profession as "mounting the loss of autonomy." Lazarus (1996) pointed out that psychologists have actively resisted managed care and the resulting reduction of mental health services in several ways. "Examples of resistance include verbally abusing utilization reviewers, involving patients and families in insurance disputes, referring medically unstable patients [illegible] provider [illegible], failing to comply with managed care procedures, and [illegible] managed care firms for [illegible]" (p. 101). Lawsuits have been directed at health maintenance organizations for failing to provide appropriate and needed services. Sleek (1997) recently described a lawsuit in which seven psychologists were suing a managed care corporation for circumventing the psychologist's judgment, denying necessary treatment [illegible], and dropping them from the managed care panel. The extent to which such clashes will adversely affect the provision of mental health services is uncertain. It appears likely, however, that conflict will be prominent over the next few years as managed care systems assume more control over the mental health system.

A number of observers have criticized the quality of mental health services offered by HMOs (Karon, 1995), citing a number of deleterious effects within the caregiving professions. Many HMOs have solved some "cost" problems by employing individuals to provide therapy who are not trained at the doctoral level. Less trained people (holders of bachelor's and master's degrees) are increasingly asked to provide therapy. Consequently, some independent psychologists and psychiatrists have left the field because of the lack of a livable income from conducting psychotherapy. We are aware of many devoted mental health practitioners who have altered their careers and moved into occupations that are not connected with health care.

Critics of managed care argue that there is no convincing evidence that current efforts are actually controlling costs (Gabbard, 1994; Harwood et al., in press) and that there is no scientific support for the limited benefit options being exercised (England, 1994). Some have pointed out that the administrative costs for managed care centers (including high salaries for HMO executives) are exorbitant. Gabbard (1994), for example, estimated that about one-fourth of the health care expenditures in the United States goes for managed care administration.

The revolution in health care has clearly created controversy in the field of psychotherapy. The mental health field is being drastically altered by economic considerations. These growing pains are likely to continue as our society attempts to come to terms with the cost of health care and the need to provide care for citizens who desperately need help. One thing appears to be certain: The nature of the mental health professions is changing. Whether these changes are for better or worse is yet to be determined.

# GLOSSARY

*Many of the key terms listed in the glossary appear in boldface when first introduced in the text discussion. A number of other terms commonly encountered in this or other psychology texts are also included; you are encouraged to make use of this glossary both as a general reference tool and as a study aid for the course in abnormal psychology.*

**Abnormal behavior.** Maladaptive behavior detrimental to an individual and/or a group.

**Abnormal psychology.** Field of psychology concerned with the study, assessment, treatment, and prevention of abnormal behavior.

**Abstinence.** Refraining altogether from the use of a particular addictive substance or from a particular behavior.

**Accommodation.** Cognitive process whereby new information causes a reorganization of previously existing cognitive frameworks.

**Activation (arousal).** Energy mobilization required for an organism to pursue its goals and meet its needs.

**Actuarial approach.** Application of probability statistics to human behavior.

**Actuarial procedures.** Methods whereby data about many subjects' behavior is stored and analyzed by computer.

**Acute (disorder).** Term used to describe a disorder of sudden onset and relatively short duration, usually with intense symptoms.

**Acute stress disorder.** Disorder following a traumatic event that occurs within four weeks of the event and lasts for a minimum of two days and a maximum of four weeks.

**Acute schizophrenia.** See **Reactive schizophrenia.**

**Addictive behavior.** Behavior based on the pathological need for a substance or activity; it may involve the abuse of substances, such as alcohol or cocaine, or excessive indulgence in food or gambling.

**Adjustment.** Outcome of a person's efforts to deal with stress and meet his or her needs.

**Adjustment disorder.** A disorder in which a person has difficulty behaving adaptively when faced with a common stressor.

**Adjustment disorder with depressed mood.** Moderately severe mood disorder similar to dysthymic disorder but having an identifiable, though not severe, psychosocial stressor occurring within three months before the onset of depression, and not exceeding six months in duration.

**Adrenal cortex.** Outer layer of the adrenal glands; secretes the adrenal steroids and other hormones.

**Adrenal glands.** Endocrine glands located at the upper end of the kidneys; consist of inner adrenal medulla and outer adrenal cortex.

**Adrenaline.** Hormone secreted by the adrenal medulla during strong emotion; causes such bodily changes as an increase in blood sugar and a rise in blood pressure. Also called *epinephrine*.

**Advocacy.** Approach to meeting mental health needs in which advocates, often an interested group of volunteers, attempt to help children or others receive services that they need but often are unable to obtain for themselves.

**Advocacy programs.** Programs aimed at helping people in underserved populations to obtain aid with which to improve their situations.

**Affect.** Emotion or feeling.

**Aftercare.** Follow-up therapy after release from a hospital.

**Aggression.** Behavior aimed at hurting or destroying someone or something.

**Agitation.** Marked restlessness and psychomotor excitement.

**Agoraphobia.** Fear of being in places or situations from which escape would be physically difficult or psychologically embarrassing, or in which help would be unavailable, should a panic attack occur.

**AIDS-dementia complex (ADC).** Generalized loss of cognitive functioning as a result of HIV-1 infection.

**AIDS-related complex (ARC).** Pre-AIDS manifestation of HIV infection involving minor infections, various nonspecific symptoms (such as unexplained fever), blood cell count abnormalities, and sometimes cognitive difficulties.

**Alarm and mobilization reaction.** First state of the general adaptation syndrome, characterized by the mobilization of defenses to cope with a stressful situation.

**Alcoholic.** Person with a serious drinking problem, whose drinking impairs life adjustment in terms of health, personal relationships, and occupational functioning.

**Alcoholism.** Dependence on alcohol that seriously interferes with life adjustment.

**Alexithymia.** Term used to denote a personality pattern in which a person is unable to communicate distress in other than somatic language.

**Alienation.** Lack or loss of relationships to others.

**Alter personalities.** In a person with dissociative identity disorder, personalities other than the host personality.

**Alzheimer's disease.** See **Dementia of the Alzheimer's type.**

**Amnesia.** Total or partial loss of memory.

**Amnestic syndrome.** Inability to remember events more than a few minutes after they have occurred or the inability to recall the recent and remote past.

**Amniocentesis.** Technique that involves drawing fluid from the amniotic sac of a pregnant woman so that the sloughed-off fetal cells can be examined for chromosomal irregularities, including that of Down syndrome.

**Amphetamine.** Drug that produces a psychologically stimulating and energizing effect.

**Analogue studies.** Studies in which a researcher attempts to simulate the conditions under investigation.

**Anal stage.** In psychoanalytic theory, stage of psychosexual development in which behavior is presumably focused on anal pleasure and activities.

**Androgen.** Hormone associated with the development and maintenance of male characteristics.

**Anesthesia.** Loss or impairment of sensitivity (usually to touch but often applied to sensitivity to pain and other senses as well).

**Anhedonia.** Inability to experience pleasure or joy.

**Anorexia nervosa.** Disorder involving severe loss of body weight, accompanied by an intense fear of gaining weight or becoming "fat."

**Anoxia.** Lack of sufficient oxygen.

**Antabuse.** Drug used in the treatment of alcoholism.

**Anterograde amnesia.** Loss of memory for events that occur *following* trauma or shock.

**Antianxiety drugs.** Drugs that are used primarily for alleviating anxiety.

**Antibody.** Circulating blood substance coded for detection of and binding to a particular antigen.

**Antidepressant drugs.** Drugs that are used primarily to elevate mood and relieve depression.

**Antigen.** Substance detected as "foreign" by the body's immune defenses, giving rise to the immune reaction.

**Antipsychotic drugs.** Group of drugs that produce a calming effect on many patients as well as alleviate or reduce the intensity of psychotic symptoms, such as delusions and hallucinations and sometimes negative symptoms.

**Antisocial personality disorder.** Personality disorder involving disregard for the rights of others, impulsivity, and aggressive and irresponsible behavior.

**Anxiety.** A generalized feeling of apprehension about possible danger.

**Anxiety disorder.** A disorder involving an unrealistic, irrational fear or anxiety of disabling intensity. DSM-IV lists seven types of anxiety disorder: phobia (specific or social), panic disorder (with or without agoraphobia), generalized anxiety disorder, obsessive-compulsive disorder, and posttraumatic stress disorder.

**Aphasia.** Loss or impairment of ability to communicate and understand language symbols—involving loss of power of expression by speech, writing, or signs, or loss of ability to comprehend written or spoken language—resulting from brain injury or disease.

**Apraxia.** Loss of ability to perform purposeful movements.

**Arousal.** See **Activation.**

**Arteriosclerosis.** Degenerative thickening and hardening of the walls of the arteries, occurring usually in old age.

**Assertiveness therapy.** Behavior therapy technique for helping people become more self-assertive in interpersonal relationships.

**Assimilation.** Cognitive process whereby new information is fitted into previously existing cognitive frameworks.

**Asylums.** Institutions established solely for the care of the mentally ill.

**At risk.** Condition of being considered vulnerable to the development of certain abnormal behaviors.

**Atrophy.** Wasting away or shrinking of a bodily organ, particularly muscle tissue.

**Attention-deficit hyperactivity disorder (ADHD).** Disorder of childhood characterized by difficulties that interfere with task-oriented behavior, such as impulsivity, excessive motor activity, and an inability to focus attention for appropriate periods of time. Also known as hyperactivity.

**Attributions.** Causes assigned to things that happen.

**Autism.** Pervasive developmental disorder beginning in infancy involving a wide range of abnormalities, including deficits in language, perceptual, and motor development; defective reality testing; and social withdrawal.

**Autonomic nervous system.** Section of the nervous system that regulates the internal organs; consists primarily of ganglia connected with the brain stem and spinal cord; may be subdivided into the sympathetic and parasympathetic systems.

**Autonomic reactivity.** Individual's characteristic degree of emotional reactivity to stress.

**Autonomy.** Self-reliance; the sense of being an independent person.

**Autosome.** Any chromosome other than those determining sex.

**Aversion therapy.** Form of behavior therapy in which punishment or aversive stimulation is used to eliminate undesired responses.

**Aversive conditioning.** Use of noxious stimuli to suppress unwanted behavior.

**Aversive stimulus.** Stimulus that elicits psychic or physical pain.

**Avoidance conditioning.** Form of conditioning in which a subject learns to behave in a certain way in order to avoid an unpleasant stimulus.

**Avoidant personality disorder.** Personality disorder characterized by hypersensitivity to rejection, limited social relationships, and low self-esteem.

**Barbiturate.** Type of synthetic sedative drug.

**Baseline.** The initial level of responses emitted by an organism.

**Behavioral contracting.** Positive reinforcement technique using a contract, often between family members, stipulating privileges and responsibilities.

**Behavioral medicine.** Broad interdisciplinary approach to the treatment of physical disorders thought to have psychological factors as major aspects of their causal patterns.

**Behavioral perspective.** A theoretical viewpoint organized around the theme that learning is central in determining human behavior.

**Behavioral sciences.** Various interrelated disciplines, including psychology, sociology, and anthropology, that focus on human behavior.

**Behavior disorder.** Synonym for psychological problem.

**Behaviorism.** School of psychology that formerly restricted itself primarily to study of overt behavior.

**Behavior modification.** Change of specific behaviors by learning techniques.

**Behavior therapy.** Therapeutic procedures based primarily on principles of classical and operant conditioning.

**Benign.** Of a mild, self-limiting nature; not malignant.

**Biofeedback.** Treatment technique in which a person is taught to influence physiological processes formerly thought to be involuntary.

**Biogenic amines.** Chemicals that serve as neurotransmitters or modulators.

**Biological clocks.** Regular biological cycles of sleep, activity, and metabolism characteristic of each species.

**Biological viewpoint.** Approach to mental disorders emphasizing biological causation.

**Bipolar disorder.** Mood disorder in which a person experiences both manic and depressive episodes.

**Bipolar disorder with a seasonal pattern.** Bipolar disorder with recurrences in particular seasons of the year.

**Bisexuality.** Sexual attraction to both females and males.

**Blocking.** Involuntary inhibition of recall, ideation, or communication (including sudden stoppage of speech).

**Blood-injury phobia.** Persistent and disproportionate fear of the sight of blood or injury.

**Borderline personality disorder.** Personality disorder characterized by instability in interpersonal relationships, self-image, and moods.

**Brain pathology.** Diseased or disordered condition of the brain.

**Brain waves.** Minute oscillations of electrical potential given off by neurons in the cerebral cortex and measured by the electroencephalograph.

**Brief Psychiatric Rating Scale (BPRS).** Objective method of rating clinical symptoms that provides scores on 18 variables (e.g., somatic concern, anxiety, withdrawal, hostility, and bizarre thinking).

**Brief psychotherapy.** Short-term therapy, usually 8 to 10 sessions, focused on restoring an individual's functioning and offering emotional support.

**Bulimia nervosa.** Recurring episodes of seemingly uncontrollable binge-eating, often accompanied by extreme efforts to purge in order to prevent weight gain.

**Caffeine.** Chemical compound found in many commonly available drinks and foods, whose negative effects can include intoxication, restlessness, nervousness, excitement, insomnia, muscle twitching, and gastrointestinal complaints.

**Cardiovascular.** Pertaining to the heart and blood vessels.

**Case study.** An in-depth examination of an individual or family.

**Castrating.** Refers to any source of injury to or deprivation of the genitals, or more broadly, to a threat to the masculinity or femininity of an individual.

**Castration anxiety.** As postulated by Freud, the anxiety a young boy experiences when he desires his mother while at the same time viewing his father as a rival and fearing that his father may harm him by removing his penis; this anxiety forces the boy to repress his sexual desire for his mother and his hostility toward his father.

**Catalepsy.** Condition in which the muscles are waxy and semirigid, tending to maintain the limbs in any position in which they are placed.

**Catecholamine.** Class of amines sharing a similar chemical structure and involved chiefly in neural transmission.

**Categorical approach.** Approach to classifying abnormal behavior that assumes that (a) all human behavior can be sharply divided into the categories normal and abnormal, and (b) there exist discrete, nonoverlapping classes or types of abnormal behavior, often referred to as mental illnesses or diseases.

**Catharsis.** Discharge of emotional tension associated with something, such as by talking about past traumas.

**CAT scan.** See **Computerized axial tomography.**

**Causal pattern.** In a cause-and-effect relationship, a situation in which more than one causal factor is involved.

**Causation.** Relationship in which the preceding variable causes the other(s).

**Central nervous system (CNS).** The brain and spinal cord.

**Cerebral arteriosclerosis.** Hardening of the arteries in the brain.

**Cerebral cortex.** Surface layers of the cerebrum.

**Cerebral hemorrhage.** Bleeding into brain tissue from a ruptured blood vessel.

**Cerebral laceration.** Tearing of brain tissue associated with severe head injury.

**Cerebral syphilis.** Syphilitic infection of the brain.

**Cerebral thrombosis.** Formation of a clot or thrombus in the vascular system of the brain.

**Cerebrovascular accident (CVA).** Blockage or rupture of large blood vessel in brain leading to both focal and generalized impairment of brain function. Also called *stroke.*

**Cerebrum.** Main part of brain; divided into left and right hemispheres.

**Chemotherapy.** Use of drugs to treat mental disorders.

**Child abuse.** Infliction of physical or psychological damage on a child by parents or other adults.

**Child advocacy.** Movement concerned with protecting rights and ensuring well-being of children.

**Chorea.** Pathological condition characterized by jerky, irregular, involuntary movements. See also **Huntington's disease.**

**Chromosomal anomalies.** Inherited defects or vulnerabilities caused by irregularities in chromosomes.

**Chromosomes.** Chainlike structures within cell nucleus that contain genes.

**Chronic.** Term used to describe a disorder that is a relatively permanent maladaptive pattern or condition.

**Chronic schizophrenia.** See **Process schizophrenia.**

**Circadian rhythms.** The 24-hour rhythmic fluctuations in sleep, activity, and metabolic processes of plants and animals. See also **Biological clocks.**

**Civil commitment.** Procedure whereby a person certified as mentally disordered can be hospitalized, either voluntarily or against his or her will.

**Classical (respondent) conditioning.** Basic form of learning in which a previously neutral stimulus comes to elicit a response that was previously only elicited by a stimulus that automatically elicited that response.

**Claustrophobia.** Irrational fear of small enclosed places.

**Client-centered (person-centered) psychotherapy.** Nondirective approach to psychotherapy developed chiefly by Carl Rogers and based on his personality theory.

**Clinical picture.** Diagnostic picture formed by observation of patient's behavior or by all available assessment data.

**Clinical problem checklist.** Computer-administered psychological assessment procedure for surveying the range of psychological problems a patient is experiencing.

**Clinical psychologist.** Mental health professional with Ph.D. degree or Psy.D. degree in clinical psychology and clinical experience in assessment and psychotherapy.

**Clinical psychology.** Field of psychology concerned with the understanding, assessment, treatment, and prevention of maladaptive behavior.

**Cocaine.** Stimulating and pain-reducing psychoactive drug.

**Cognition.** Act, process, or product of knowing or perceiving.

**Cognitive-behavioral perspective.** A theory of abnormal behavior that focuses on how thoughts and information processing can become distorted and lead to maladaptive emotions and behavior.

**Cognitive-behavior therapy.** Therapy based on altering dysfunctional thoughts and cognitive distortions.

**Cognitive dissonance.** Condition of tension existing when several of one's beliefs and attitudes are inconsistent with one another.

**Cognitive map.** Network of assumptions that form a person's "frame of reference" for interpreting and coping with his or her world.

**Cognitive processes (cognition).** Mental processes, including perception, memory, and reasoning, by which one acquires knowledge, solves problems, and makes plans.

**Cognitive restructuring.** Cognitive-behavioral therapy that aims to change a person's false or maladaptive frame of reference.

**Collective unconscious.** Term used by Carl Jung to refer to that portion of the unconscious that he considered common to all humanity.

**Coma.** Profound stupor with unconsciousness.

**Community mental health.** Application of psychosocial and sociocultural principles to the improvement of given environments.

**Community psychology.** Use of community resources in dealing with maladaptive behavior; tends to be more concerned with community intervention rather than with personal or individual change.

**Compulsions.** Repetitive behaviors or mental acts such as cleaning or checking that a person feels driven to perform in response to an obsession.

**Compulsive gambling.** See **Pathological gambling.**

**Computer assessment.** Use of computers to obtain or interpret assessment data.

**Computerized axial tomography (CAT scan).** Radiological technique used to locate and assess the extent of organic damage without surgery.

**Concordance rates.** The percentage of twins who share a diagnosis or trait.

**Conditioning.** Simple form of learning involving stimulus and response. See also **Classical conditioning** and **Operant conditioning.**

**Conduct disorders.** Childhood disorders marked by persistent acts of aggressive or antisocial behavior that may or may not be against the law.

**Confabulation.** Filling in of memory gaps with false and often irrelevant details.

**Confidentiality.** Commitment on part of a professional person to keep information he or she obtains from a client confidential.

**Conflict.** Simultaneous arousal of opposing impulses, desires, or motives.

**Congenital.** Existing at birth or before birth but not necessarily hereditary.

**Congenital defect.** Genetic defect or environmental condition occurring before birth and causing a child to develop a physical or psychological anomaly.

**Consciousness.** Awareness of inner and/or outer environment.

**Constitution.** Relatively constant biological makeup of an individual, resulting from the interaction of heredity and environment.

**Constitutional liability.** Any detrimental characteristic that is either innate or acquired so early and in such strength that it is functionally similar to a genetic characteristic.

**Consultation.** Community intervention approach that aims at helping individuals at risk for disorder by working indirectly through caretaker institutions (e.g., police and teachers).

**Contingency.** Relationship, usually causal, between two events in which one is usually followed by the other.

**Continuous reinforcement.** Reward or reinforcement given regularly after each correct response.

**Control group.** Group of subjects compared with an experimental group in assessing the effects of independent variables.

**Contributory cause.** A condition that increases the probability of developing a disorder but that is neither necessary nor sufficient for it to occur.

**Conversion disorder.** Type of somatoform disorder in which pseudoneurological symptoms of some physical malfunction or loss of control appear without any underlying organic pathology; previously called *hysteria.*

**Convulsion.** Pathological, involuntary muscular contractions.

**Coping strategies.** Efforts used to deal with stress.

**Coprolalia.** Verbal tic in which an individual utters obscenities aloud.

**Coronary heart disease (CHD).** Potentially lethal blockage of the arteries supplying blood to the heart muscle, or myocardium.

**Corpus callosum.** Nerve fibers that connect the two hemispheres of the brain.

**Correlation.** The tendency of two variables to covary. With positive correlation, as one variable goes up, so does the other; with negative correlation as one variable goes up the other goes down.

**Corticovisceral control mechanisms.** Brain mechanisms that regulate autonomic and other bodily functions.

**Counseling psychology.** Field of psychology that focuses on helping people with problems pertaining to education, marriage, or occupation.

**Counter-transference.** In psychodynamic therapy, inappropriate feelings of transference on the part of the therapist toward the client.

**Couples counseling (marital therapy).** Treatment for disordered interpersonal relationships involving sessions with both members of the relationship present.

**Coverants.** Internal, private events, such as thoughts and assumptions, to which conditioning principles are applied in cognitive-behavioral therapy.

**Covert.** Concealed, disguised, not directly observable.

**Covert sensitization.** Behavioral treatment method for extinguishing undesirable behavior by associating noxious mental images with that behavior.

**Criminal responsibility.** Legal question of whether a person should be permitted to use insanity as a defense after having committed a crime.

**Crisis.** Stress situation that approaches or exceeds adaptive capacities of an individual or group.

**Crisis intervention.** Various methods for rendering therapeutic assistance to an individual or group during a period of crisis.

**Criterion group.** Group of subjects who exhibit the variable or disorder under study.

**Cross-gender identification.** The desire to be, or the insistence that one is, of the opposite sex.

**Cultural-familial retardation.** Mental retardation as a result of an inferior quality of interaction with the cultural environment and with other people, with no evidence of brain pathology.

**Cultural relativism.** Position that one cannot apply universal standards of normality or abnormality to all societies.

**Cyclothymia.** Mild mood disorder characterized by cyclical periods of hypomanic and depressive symptoms.

**Day hospital.** Community-based mental hospital where patients are treated during the day, returning to their homes at night.

**Decompensation**. Loss of adaptive functioning under excessive stress.

**Defense mechanism.** See **Ego-defense mechanism.**

**Defense-oriented response.** Behavior directed primarily at protecting the self from hurt and disorganization rather than at coping with the demands of a stressor.

**Deinstitutionalization.** Movement to provide chronic patients with continued psychiatric care in the local community rather than committing them to institutions.

**Delinquency.** Antisocial or illegal behavior by a minor.

**Delirium.** State of mental confusion characterized by relatively rapid onset of widespread disorganization of the higher mental processes, caused by a generalized disturbance in brain metabolism. May include impaired perception, memory, and thinking and abnormal psychomotor activity.

**Delirium tremens.** Acute delirium associated with prolonged alcoholism; characterized by intense anxiety, tremors, and hallucinations.

**Delusion.** Firm belief opposed to reality but maintained in spite of strong evidence to the contrary.

**Delusional disorder.** Type of psychosis characterized by a systematized delusional system; formerly called ***paranoia*** and ***paranoid disorder.***

**Delusional system.** Internally coherent, systematized pattern of delusions.

**Delusion of grandeur.** False belief that one is a noted or famous person, such as Napoleon or the Virgin Mary.

**Delusion of persecution.** False belief that one is being mistreated or interfered with by one's enemies.

**Dementia.** Progressive deterioration of brain functioning occurring after the completion of brain maturation in adolescence. Characterized by deficits in memory, thinking, and behavior.

**Dementia of the Alzheimer's type (DAT).** Disorder associated with a progressive dementia syndrome ultimately terminating in death. Onset may be in middle or old age, and symptoms include memory loss, withdrawal, confusion, and impaired judgment.

**Dementia praecox.** Older term for schizophrenia.

**Demonology.** Viewpoint emphasizing supernatural causation of mental disorder, especially "possession" by evil spirits or forces.

**Denial of reality.** Ego-defense mechanism by means of which a person protects himself or herself from unpleasant aspects of reality by refusing to acknowledge them.

**Dependency.** Tendency to rely overly on others.

**Dependent personality disorder.** Personality disorder marked by clinging and submissive behavior and feelings of panic or discomfort at having to be alone.

**Dependent variable.** In an experiment, the factor that the hypothesis predicts will change with changes in the independent variable.

**Depersonalization.** Loss of sense of personal identity, often with a feeling of being something or someone else.

**Depersonalization disorder.** Dissociative disorder in which there is a loss of the sense of self.

**Depression.** Emotional state characterized by extreme sadness and dejection.

**Depressive personality disorder.** Provisional personality disorder in DSM-IV that involves a pattern of depressive cognitions that begins in early childhood and is pervasive in nature.

**Derealization.** Experience in which the external world is perceived as distorted and as lacking a stable and palpable existence.

**Desensitization.** Therapeutic process by means of which reactions to traumatic experiences are reduced in intensity by repeatedly exposing a person to them in mild form, either in reality or in fantasy, while remaining in a state of relaxation.

**Desire phase.** First phase of the human sexual response, consisting of fantasies about sexual activity or a sense of desire to have sexual activity.

**Deterrence.** Premise that punishment for criminal offenses will deter that criminal and others from future criminal acts.

**Detox.** Center or facility for receiving and detoxifying alcohol- or drug-intoxicated individuals.

**Detoxification.** Treatment directed toward ridding the body of alcohol or other drugs.

**Developmental disorder.** Problem that is rooted in deviations in the development process itself, thus disrupting the acquisition of skills and adaptive behavior and often interfering with the transition to well-functioning adulthood.

**Developmental psychopathology.** Field of psychology that studies disorders of childhood within the context of developmental processes.

**Deviant behavior.** Behavior that deviates markedly from the average or norm.

**Diagnosis.** Determination of the nature and extent of a specific disorder.

**Diathesis.** Predisposition or vulnerability toward developing a given disorder.

**Diathesis-stress model.** View of abnormal behavior as the result of stress operating on an individual with a biological, psychosocial, or sociocultural predisposition toward developing a specific disorder.

**Dimensional approach.** Approach to classifying abnormal behavior that assumes that a person's typical behavior is the product of differing strengths or intensities of behavior along several definable dimensions, such as mood, emotional stability, aggressiveness, gender, identity, anxiousness, interpersonal trust, clarity of thinking and communication, social introversion, and so on.

**Directive therapy.** Type of therapeutic approach in which a therapist supplies direct answers to problems and takes much of the responsibility for the progress of therapy.

**Disaster syndrome.** Response pattern that appears to characterize the initial and long-lasting reactions of many victims of catastrophes.

**Discordant marriage.** Family in which one or both of the parents is not gaining satisfaction from the relationship and one spouse may express frustration and disillusionment in hostile ways, such as nagging, belittling, and purposely doing things to annoy the other person.

**Discrimination.** Learning to interpret and respond differently to two or more similar stimuli.

**Disintegration.** Loss of organization or integration in any organized system.

**Disorganization.** Severely impaired integration.

**Disorientation.** Mental confusion with respect to time, place, or person.

**Displacement.** Ego-defense mechanism in which an emotional attitude or symbolic meaning is transferred from one object or concept to another.

**Disrupted family.** Family that is incomplete as a result of death, divorce, separation, or some other circumstance.

**Dissociation.** The human mind's capacity to mediate complex mental activity in channels split off from or independent of conscious awareness.

**Dissociative amnesia.** Psychogenically caused memory failure.

**Dissociative disorders.** Conditions involving a disruption in the sense of a coherent and stable personal identity.

**Dissociative identity disorder.** Condition in which a person manifests two or more complete systems of personality. Formerly called ***multiple personality disorder.***

**Distress.** Negative stress, leading to sorrow, anguish, or sense of misfortune.

**Disturbed family.** Family in which one or both parents behave in grossly eccentric or abnormal ways and may keep the home in constant emotional turmoil.

**Dizygotic (fraternal) twins.** Twins that develop from two separate eggs.

**DNA.** Deoxyribonucleic acid, principal component of genes.

**Dominant gene.** A gene whose hereditary characteristics prevail in the offspring.

**Dopamine.** Catecholamine neurotransmitter substance.

**Dopamine hypothesis.** Hypothesis that schizophrenia is the result of an excess of dopamine activity at certain synaptic sites.

**Double-bind.** Situation in which a person will be disapproved for performing a given act and equally disapproved if he or she does not perform it.

**Double-bind communication.** Type of faulty communication in which the one person (e.g., a parent) presents to another (e.g., a child) ideas, feelings, and demands that are mutually incompatible.

**Down syndrome.** Form of moderate to severe mental retardation associated with chromosomal abnormality and typically accompanied by characteristic physical features.

**Dream analysis.** Psychotherapeutic technique involving the interpretation of a patient's dreams.

**Drive.** Internal conditions directing an organism toward a specific goal, usually involving biological rather than psychological motives.

**Drug abuse.** Use of a drug to the extent that it interferes with health and/or occupational or social adjustment.

**Drug addiction (dependence).** Physiological and/or psychological dependence on a drug.

**Drug therapy.** See **Chemotherapy** and **Pharmacotherapy.**

**DSM-IV.** Current diagnostic manual of the American Psychiatric Association.

**Dwarfism.** Condition of arrested growth and very short stature.

**Dyad.** Two-person group.

**Dynamic formulation.** Integrated evaluation of a client's traits, attitudes, conflicts, and symptoms that attempts to explain his or her problem.

**Dysfunction.** Impairment or disturbance in the functioning of an organ or in behavior.

**Dysfunctional beliefs.** Negative beliefs that are rigid, extreme, and counterproductive.

**Dyslexia.** Impairment of the ability to read.

**Dyspareunia.** Painful coitus in a male or a female.

**Dysrhythmia.** Abnormal brain-wave pattern.

**Dysthymia.** Moderately severe mood disorder characterized by extended periods of nonpsychotic depression and brief periods of normal moods.

**Echolalia.** Meaningless repetition of words by an individual, usually of whatever has been said to that person.

**Edema.** Swelling of tissues.

**EEG.** See **Electroencephalogram.**

**Ego.** In psychoanalytic theory, the rational subsystem of the personality that mediates between id and superego demands and reality. More generally, a person's self-concept.

**Egocentric.** Preoccupied with one's own concerns and relatively insensitive to the concerns of others.

**Ego-defense mechanism.** Psychic mechanism that acts to maintain a person's feelings of adequacy and worth rather than to cope directly with an anxiety-provoking situation; usually unconscious and reality-distorting. Also called ***defense mechanism.***

**Electra complex.** In psychoanalytic theory, an excessive emotional attachment (love) of a daughter for her father.

**Electroconvulsive therapy (ECT).** Use of electricity to produce convulsions and unconsciousness; a treatment used primarily for severe depression. Also known as ***electroshock therapy.***

**Electroencephalogram (EEG).** Graphic record of the brain's electrical activity, obtained by placing electrodes on the scalp and measuring the brain-wave impulses from various brain areas.

**Embolism.** Lodgment of a blood clot in a blood vessel too small to permit its passage.

**Emotion.** Strong feeling accompanied by physiological changes.

**Emotional disturbance.** Psychological disorder.

**Emotional insulation.** Ego-defense mechanism in which a person reduces anxiety by withdrawing into a shell of passivity.

**Empathy.** Ability to understand and to some extent share the state of mind of another person.

**Encephalitis.** Inflammation of the brain.

**Encopresis.** Disorder defined by having bowel movements in one's clothing after the age of four.

**Encounter group.** Small group designed to provide an intensive interpersonal experience focusing on feelings and group interactions; used in therapy or to promote personal growth.

**Endocrine glands.** Ductless glands that secrete hormones directly into the lymph or bloodstream.

**Endogenous factors.** Factors originating within an organism that affect behavior.

**Endorphins.** Opiate-like substances produced in the brain and pituitary gland in response to stimulation; thought to play a role in an organism's reaction to pain.

**Enuresis.** Bed wetting; involuntary discharge of urine after the age of expected continence (age five).

**Environmental psychology.** Field of psychology focusing on the effects of an environmental setting on an individual's feelings and behavior.

**Epidemiology.** Study of the distribution of diseases, disorders, or health-related behaviors in a given population. Mental health epidemiology is the study of the distribution of mental disorders.

**Epilepsy.** Group of disorders varying from momentary lapses of consciousness to generalized convulsions.

**Epinephrine.** Hormone secreted by the adrenal medulla; also called ***adrenaline.***

**Episodic (disorder).** Term to describe a disorder that tends to abate and to recur.

**Equilibrium.** Steady state; balance.

**Erectile insufficiency.** Inability of a male to achieve erection.

**Erotic.** Pertaining to sexual stimulation and gratification.

**Escape learning.** Conditioned response in which a subject learns to terminate or escape an aversive stimulus.

**Essential hypertension.** High blood pressure with no known physical cause.

**Estrogens.** Female hormones produced by the ovaries.

**Ethnic group.** Group of people who are treated as distinctive in terms of culture and group patterns.

**Etiology.** Causation; the systematic study of the causes of disorders.

**Euphoria.** Exaggerated feeling of well-being and contentment.

**Eustress.** Positive stress.

**Exacerbate.** Intensify.

**Excitement phase.** Phase of the human sexual response in which there is a subjective sense of sexual pleasure and physiological changes, including penile erection in the male and vaginal lubrication and enlargement in the female.

**Exhaustion and disintegration.** Third and final stage in the general adaptation syndrome, in which an organism is no longer able to resist continuing stress; at the biological level may result in death.

**Exhibitionism.** Public display or exposure of genitals to others in inappropriate circumstances and without their consent.

**Existential anxiety.** Anxiety concerning one's ability to find a satisfying and fulfilling way of life.

**Existentialism.** View of human beings that emphasizes an individual's responsibility for becoming the kind of person he or she should be.

**Existential neurosis.** Disorder characterized by feelings of alienation, meaninglessness, and apathy.

**Existential psychotherapy.** Type of therapy that is based on existential thought and focuses on individual uniqueness and authenticity on the part of both client and therapist.

**Exogenous.** Originating from or due to external causes.

**Exorcism.** Religiously inspired treatment procedure designed to drive out evil spirits or forces from a "possessed" person.

**Experimental group.** Group of subjects used to assess the effects of independent variables.

**Experimental method.** Rigorous scientific procedure by which hypotheses are tested.

**Expressed emotion (EE).** Type of negative communication involving excessive criticism and emotional overinvolvement directed at a patient by family members.

**Extinction.** Gradual disappearance of a conditioned response when it is no longer reinforced.

**Extraversion.** Personality type oriented toward the outer world of people and things rather than concepts and intellectual concerns.

**Factitious disorders.** Conditions in which symptoms are feigned in order to satisfy the psychological need to assume and maintain a sick role.

**Factor analysis.** Statistical technique used for reducing a large array of intercorrelated measures to the minimum number of factors necessary to account for the observed overlap among them.

**Fading.** Technique whereby a stimulus causing some reaction is gradually replaced by a previously neutral stimulus, such that the latter acquires the property of producing the reaction in question.

**False memories.** "Memories" of events that did not actually happen, often produced by highly leading and suggestive techniques.

**Familial.** Pertaining to characteristics that tend to run in families and have a higher incidence in certain families than in the general population.

**Family therapy.** Form of interpersonal therapy focusing on relationships within a family.

**Fantasy.** Daydream; also, an ego-defense mechanism by means of which a person escapes from the world of reality and gratifies his or her desires in fantasy achievements.

**Fear.** A basic emotion that involves activation of the "fight or flight" response.

**Feedback.** Explicit information pertaining to internal physiological processes or to the social consequences of one's overt behavior.

**Female orgasmic disorder.** Persistent or recurrent delay in or absence of orgasm following a normal sexual excitement phase.

**Female sexual arousal disorder.** Sexual dysfunction involving an absence of sexual arousal feelings and unresponsiveness to most or all forms of erotic stimulation.

**Fetal alcohol syndrome.** Observed pattern in infants of alcoholic mothers in which there is a characteristic facial or limb irregularity, low body weight, and behavioral abnormality.

**Fetishism.** Sexual variant in which sexual interest centers on some inanimate object or nonsexual part of the body.

**Fetus.** Embryo after the sixth week following conception.

**Fixation.** In psychoanalytic theory, unreasonable or exaggerated attachment to some person or arresting of emotional development on a childhood or adolescent level.

**Fixed-interval schedule.** Schedule of reinforcement based on fixed period of time after previous reinforced response.

**Fixed-ratio schedule.** Schedule of reinforcement based on reinforcement after fixed number of nonreinforced responses.

**Flashback.** Involuntary recurrence of perceptual distortions or hallucinations weeks or months after taking a drug; in post-traumatic stress disorder, a dissociative state in which the person briefly relives the traumatic experience.

**Flooding.** Anxiety-eliciting technique involving placing a client in a real-life, anxiety-arousing situation.

**Folie à deux.** See **Shared psychotic disorder.**

**Follow-up study.** Research procedure in which people are studied over a period of time or are recontacted at a later time after initial study.

**Forensic psychology and psychiatry.** Branches of psychology and psychiatry dealing with legal problems relating to mental disorders.

**Fraternal twins.** Dizygotic twins; fertilized by separate germ cells, thus not having same genetic inheritance. May be of the same or opposite sex.

**Free association.** Psychoanalytic procedure for probing the unconscious in which a person gives a running account of every thought and feeling.

**Free-floating anxiety.** Anxiety not referable to any specific situation or cause.

**Frontal lobe.** Portion of the brain active in reasoning and other higher thought processes.

**Frustration.** Thwarting of a need or desire.

**Frustration tolerance.** See **Stress tolerance.**

**Fugue.** Dissociative disorder that entails loss of memory accompanied by actual physical flight from one's present life situation to a new environment or less threatening former one.

**Functional psychoses.** Severe mental disorders for which a specific organic pathology has not been demonstrated.

**Gambling.** Wagering on games or events in which chance largely determines the outcome.

**Gender dysphoria.** Persistent discomfort about one's biological sex or the sense that the gender role of that sex is inappropriate.

**Gender identity.** Individual's identification as being male or female.

**Gender identity disorder.** Identification with members of the opposite sex, and persistent discomfort with one's anatomical sexual identity.

**General adaptation syndrome (GAS).** A model of a person's reaction to excessive stress; consists of the alarm reaction, the stage of resistance, and exhaustion.

**Generalization.** Tendency of a response that has been conditioned to one stimulus to be elicited by other, similar stimuli.

**Generalized anxiety disorder.** Anxiety disorder characterized by chronic excessive worry about a number of events or activities, with no obvious threat present, as well as by a variety of symptoms of tension, irritability, or restlessness.

**Generalized reinforcer.** Reinforcer, such as money, that may influence a wide range of stimuli and behaviors.

**General paresis.** Mental disorder associated with syphilis of the brain.

**Genes.** Ultramicroscopic areas of DNA that are responsible for the transmission of hereditary traits.

**Genetic code.** Means by which DNA controls the sequence and structure of proteins manufactured within each cell and also makes exact duplicates of itself.

**Genetic counseling.** Counseling prospective parents concerning the probability of their having defective offspring as a result of genetic defects.

**Genetic inheritance.** Potential for development and behavior determined at conception by egg and sperm cells.

**Genetics.** Science of the inheritance of traits and the mechanisms of this inheritance.

**Genitalia.** Organs of reproduction, especially the external organs.

**Genital stage.** In psychoanalytic theory, the final stage of psychosexual development involving shift from autoeroticism to heterosexual interest.

**Genotype.** Genetic characteristics inherited by an individual.

**Geriatrics.** Science of the diseases and treatment of the aged.

**Germ cells.** Reproductive cells (female ovum and male sperm) that unite to produce a new individual.

**Gerontology.** Science dealing with the study of old age.

**Gestalt psychology.** School of psychology that emphasizes patterns rather than elements or connections, taking the view that the whole is more than the sum of its parts.

**Gestalt therapy.** Type of psychotherapy emphasizing wholeness of the person and integration of thought, feeling, and action.

**Gigantism.** Abnormally tall stature resulting from hyperfunctioning of the pituitary.

**Glucocorticoids.** Adrenocortical hormones involved in sugar metabolism but also having widespread effects on injury-repair mechanisms and resistance to disease; they include hydrocortisone, corticosterone, and cortisone.

**Gonads.** Sex glands.

**Good premorbid schizophrenia.** See **Reactive schizophrenia.**

**Group therapy.** Psychotherapy with two or more people at the same time.

**Guilt.** Feelings of culpability arising from behavior or desires contrary to one's ethical principles. Involves both self-devaluation and apprehension growing out of fears of punishment.

**Habit.** Any product of learning, whether it is a customary or transitory mode of response.

**Habituation.** Process whereby a person's response to the same stimulus lessens with repeated presentations.

**Halfway house.** Facility that provides aftercare following institutionalization, seeking to ease a person's adjustment to the community.

**Hallucination.** A perception in which things are seen or heard that are not real or present.

**Hallucinogens.** Drugs or chemicals capable of producing hallucinations.

**Hallucinosis.** Persistent hallucinations in the presence of known or suspected organic brain pathology.

**Hashish.** Strongest drug derived from the hemp plant; a relative of marijuana that is usually smoked.

**Health psychology.** Subspecialty within behavioral medicine that deals with psychology's contributions to diagnosis, treatment, and prevention of these psychological components of physical illnesses.

**Hebephrenic schizophrenia.** See **Schizophrenia, disorganized type.**

**Hemiplegia.** Paralysis of one lateral half of the body.

**Heredity.** Genetic transmission of characteristics from parents to their children.

**Hermaphroditism.** Anatomical sexual abnormality in which a person has sex organs of both sexes.

**Heroin.** Powerful psychoactive drug, chemically derived from morphine, that relieves pain but is even more intense and addictive than morphine.

**Heterosexuality.** Sexual interest in a member of the opposite sex.

**Hierarchy of needs.** Concept that needs arrange themselves in a hierarchy in terms of importance, from the most basic biological needs to those psychological needs concerned with self-actualization.

**High-risk.** Term applied to persons showing great vulnerability to physical or mental disorders.

**Histrionic personality disorder.** A personality disorder characterized by excessive attention-seeking, emotional instability, and self-dramatization.

**Homeostasis.** Tendency of organisms to maintain conditions making possible a constant level of physiological functioning.

**Homosexuality.** Sexual preference for a member of one's own sex.

**Hormones.** Chemicals released by the endocrine glands that regulate development of and activity in various bodily organs.

**Hostility.** Emotional reaction or drive toward the destruction or damage of an object interpreted as a source of frustration or threat.

**Host personality.** The principal personality in a person with dissociative identity disorder.

**Humanistic-experiential therapies.** Psychotherapies emphasizing personal growth and self-direction.

**Humanistic perspective.** Approach to understanding abnormal behavior that views basic human nature as "good" and emphasizes people's inherent capacity for growth and self-actualization.

**Huntington's disease.** Incurable disease of hereditary origin, which is manifested in jerking, twitching movements and mental deterioration. Formerly called *Huntington's chorea.*

**Hydrocephalus.** Relatively rare condition in which the accumulation of an abnormal amount of cerebrospinal fluid within the cranium causes damage to the brain tissues and enlargement of the skull.

**Hydrotherapy.** Use of hot or cold baths, ice packs, etc., in treatment.

**Hyper-.** Prefix meaning increased or excessive.

**Hyperactivity.** See **Attention-deficit hyperactivity disorder.**

**Hyperobesity.** Extreme overweight; more than 100 pounds over ideal body weight.

**Hypertension.** High blood pressure.

**Hyperthymic temperament.** Personality type involving lifelong hypomanic adjustment.

**Hyperventilation.** Rapid breathing associated with intense anxiety.

**Hypesthesia.** Partial loss of sensitivity.

**Hypnosis.** Trancelike mental state induced in a cooperative subject by suggestion.

**Hypnotherapy.** Use of hypnosis in psychotherapy.

**Hypo-.** Prefix meaning decreased or insufficient.

**Hypoactive sexual desire disorder.** Sexual dysfunction in which either a man or a woman shows little or no sexual drive or interest.

**Hypochondriacal delusions.** Delusions concerning various horrible disease conditions, such as the belief that one's brain is turning to dust.

**Hypochondriasis.** Condition dominated by preoccupation with bodily processes and fear of presumed diseases.

**Hypomania.** Mild form of mania.

**Hypothalamus.** Key structure at the base of the brain; important in emotion and motivation.

**Hypothesis.** Statement or proposition, usually based on observation, which is tested in an experiment; may be denied or supported by experimental results but never conclusively proved.

**Hypoxia.** Insufficient delivery of oxygen to an organ, especially the brain.

**Hysteria.** Older term used for conversion disorders; involves the appearance of symptoms of organic illness in the absence of any related organic pathology.

**ICD-10.** See **International Classification of Diseases.**

**Id.** In psychoanalytic terminology, the reservoir of instinctual drives; the most inaccessible and primitive stratum of the mind.

**Identical twins.** Monozygotic twins; developed from a single fertilized egg.

**Identification.** Ego-defense mechanism in which a person identifies himself or herself with some person or institution, usually of an illustrious nature.

**Ideology.** System of beliefs.

**Illusion.** Misinterpretation of sensory data; false perception.

**Immaturity.** Pattern of childhood maladaptive behaviors suggesting lack of adaptive skills.

**Immune reaction.** Complex defensive reaction initiated on detection of an antigen invading the body.

**Immune system.** The body's principal means of defending itself against the intrusion of foreign substances.

**Implicit memory.** Memory that occurs wthout awareness.

**Implicit perception.** Perception that occurs below the conscious level.

**Implosion.** Therapeutic technique in which clients are asked to imagine and relive aversive scenes associated with the anxiety; the assumption here is that, with repeated exposure in a "safe" setting, the aversive stimulus will lose its power to elicit anxiety.

**Implosive therapy.** Type of behavior therapy in which extinction of anxiety is achieved by eliciting, through the imagination, a massive implosion of anxiety.

**Incentive.** External inducement to behave in a certain way.

**Incest.** Culturally prohibited sexual relations between family members, such as a brother and sister or a parent and child.

**Incidence.** Occurrence rate of a given disorder in a given population.

**Independent variable.** Factor whose effects are being examined in an experiment; it is manipulated in some way while the other variables are held constant.

**Index case.** In a genetic study, an individual who evidences the trait in which the investigator is interested. Same as **proband.**

**Infantile autism.** See **Autism.**

**Inhibition.** Restraint of impulse or desire.

**Innate.** Inborn.

**Inpatient.** Hospitalized patient.

**Insanity.** Legal term for mental disorder, implying lack of responsibility for one's acts and inability to manage one's affairs.

**Insanity defense.** "Not guilty by reason of insanity" plea used as a legal defense in criminal trials.

**Insight.** Clinically, a person's understanding of his or her illness or of the motivations underlying a behavior pattern; in general psychology, the sudden grasp or understanding of meaningful relationships in a situation.

**Insight therapy.** Type of psychotherapy focusing on helping a client achieve greater self-understanding with respect to his or her motives, values, coping patterns, and so on.

**Insomnia.** Difficulty in sleeping.

**Instinct.** Inborn tendency to particular behavior patterns under certain conditions in the absence of learning.

**Instrumental (operant) conditioning.** Type of conditioning in which a subject is reinforced for making a predetermined response, such as pressing a lever.

**Insulin coma therapy.** Biological treatment that involves administration of increasing amounts of insulin until a patient goes into shock; the treatment is extremely dangerous and rarely used today.

**Intellectualization.** Ego-defense mechanism by which a person achieves some measure of insulation from emotional hurt by cutting off or distorting the emotional charge that normally accompanies hurtful situations.

**Intelligence.** The ability to learn, reason, and adapt.

**Intelligence quotient (IQ).** Measurement of "intelligence" expressed as a number or position on a scale.

**Intelligence test.** Test used in establishing a subject's level of intellectual capability.

**Interdisciplinary (multidisciplinary) approach.** Integration of various scientific disciplines in understanding, assessing, treating, and preventing mental disorders.

**Intermittent reinforcement.** Reinforcement given intermittently rather than after every response.

**International Classification of Diseases (ICD-10).** System of classification of disorders published by the World Health Organization.

**Interoceptive fears.** Fears of various internal bodily sensations.

**Interpersonal accommodation.** Reciprocal process of give and take meant to promote satisfactory interpersonal relationships.

**Interpersonal perspective.** Approach to understanding abnormal behavior that views much of psychopathology as rooted in maladaptive behavior we have learned while dealing with our interpersonal environments; it thus focuses on our relationships, past and present, with other people.

**Intrapsychic conflict.** Psychoanalytic concept referring to conflict between the id, ego, and superego.

**Introjection.** Internal process by which a child incorporates symbolically, through images and memories, some person viewed with strong emotion.

**Intromission.** Insertion of the penis into the vagina or anus.

**Introspection.** Observing (and often reporting on) one's inner experiences.

**Introversion.** Direction of interest toward one's inner world of experience and toward concepts rather than external events and objects.

**In vivo.** Taking place in a real-life situation as opposed to the therapeutic or laboratory setting.

**Ionizing radiation.** Form of radiation; major cause of gene mutations.

**Isolation.** Ego-defense mechanism by means of which contradictory attitudes or feelings that normally accompany particular attitudes are kept apart, thus preventing conflict or hurt.

**Juvenile delinquency.** Legal term used to refer to illegal acts committed by individuals under the age of 16, 17, or 18 (depending on state law).

**Juvenile paresis.** General paresis in children, usually of congenital origin.

**Klinefelter's syndrome.** Type of mental retardation associated with sex chromosome anomaly.

***La belle indifférence.*** Unconcern about serious illness or disability that is characteristic of conversion disorder.

**Labeling.** Assigning a person to a particular diagnostic category, such as schizophrenia.

**Lability.** Instability, particularly with regard to affect.

**Latency stage.** In psychoanalytic theory, a stage of psychosexual development during which sexual motivations recede in importance and a child is preoccupied with developing skills and other activities.

**Latent.** Inactive or dormant.

**Latent content.** In psychoanalytic theory, repressed motives indirectly expressed in the manifest content of dreams.

**Law of effect.** Principle that responses that have rewarding consequences are strengthened and those that have aversive consequences are weakened or eliminated.

**Learned helplessness theory of depression.** A cognitive theory of depression that suggests that an organism that learns that it has no control over aversive events will show motivational, cognitive, and emotional deficits that are similar to those shown by depressed persons.

**Learning.** Modification of behavior as a consequence of experience.

**Learning disabled (LD).** Term used to describe children who exhibit deficits in academic skills.

**Lesbian.** Female homosexual.

**Lesion.** Anatomically localized area of tissue pathology in an organ.

**Lethality scale.** Criteria used to assess the likelihood of a person's committing suicide.

**Libido.** In general psychoanalytic terminology, the instinctual drives of the id, the basic energy of life. In a narrow sense, the drive for sexual gratification.

**Life crisis.** Stress situation that approaches or exceeds a person's adjustive capacity.

**Life history method.** Technique of psychological observation in which the development of particular forms of behavior is traced by means of records of a subject's past or present behavior.

**Lifestyle.** General pattern of assumptions, motives, cognitive styles, and coping techniques that characterize a person's behavior and give it consistency.

**Lifetime prevalence.** The proportion of persons in a population who have ever had a disorder.

**Lobotomy.** See **Prefrontal lobotomy.**

**Locomotor ataxia.** Muscular incoordination usually resulting from syphilitic damage to the spinal-cord pathways.

**LSD (lysergic acid diethylamide).** Potent chemically synthesized hallucinogen that is odorless, colorless, and tasteless and that can produce intoxication with an amount smaller than a grain of salt.

**Lunacy.** Old term roughly synonymous with insanity.

**Lycanthropy.** Delusion of being a wolf.

**Lymphocyte.** Generalized term for white blood cells involved in immune protection.

**Macrocephaly.** Type of mental retardation characterized by an increase in the size and weight of the brain as a result of abnormal growth of glial cells in the brain.

**Macrophage.** Literally, "big eater." A white blood cell that destroys antigens by engulfment.

**Madness.** Nontechnical synonym for severe mental disorder.

**Mainstreaming.** Placement of mentally retarded children in regular school classrooms for all or part of the day.

**Major depressive disorder.** Severe mood disorder in which only depressive episodes occur. Besides depression, the disorder involves other symptoms such as fatigue, sleep disturbance, loss of appetite and weight, psychomotor slowing, difficulty concentrating, self-denunciation, and guilt.

**Major tranquilizers.** Antipsychotic drugs, such as the phenothiazines.

**Maladaptive (abnormal) behavior.** Behavior that is detrimental to the well-being of an individual and/or group.

**Maladjustment.** More or less enduring failure of adjustment; lack of harmony with self or environment.

**Male erectile disorder.** Sexual dysfunction in which a male is unable to achieve or maintain an erection sufficient for successful sexual intercourse.

**Male orgasmic disorder.** Retarded ejaculation or the inability to ejaculate during intercourse.

**Malingering.** Faking illness or disability symptoms consciously in order to gain some specific objective.

**Mania.** Emotional state characterized by intense and unrealistic feelings of excitement and euphoria.

**Manic-depressive psychoses.** Older term denoting a group of psychotic disorders characterized by prolonged periods of excitement and overactivity (mania) or by periods of depression and underactivity (depression) or by alternation of the two. Now known as *bipolar disorders.*

**Manifest content.** In psychoanalytic theory, the apparent meaning of a dream; masks the latent content.

**Marijuana.** Mild hallucinogenic drug derived from the hemp plant, often smoked in cigarettes called reefers or joints.

**Marital schism.** Marriage characterized by severe chronic discord that threatens continuation of the marital relationship.

**Marital skew.** Marriage maintained at the expense of a distorted relationship.

**Marital therapy.** See **Couples counseling.**

**Masked disorder.** "Masking" of underlying depression or other emotional disturbance by delinquent behavior or other patterns seemingly unrelated to the basic disturbance.

**Masochism.** Sexual variant in which a person obtains sexual pleasure from experiencing pain or humiliation.

**Mass hysteria.** Group outbreak of hysterical reactions.

**Masturbation.** Self-stimulation of genitals for sexual gratification.

**Maternal deprivation.** Lack of adequate care and stimulation by the mother or mother surrogate.

**Maturation.** Process of development and body change resulting from heredity rather than learning.

**Medical model.** View of disordered behavior as a symptom of a disease process, rather than a pattern representing faulty learning or cognition.

**Melancholic type.** Subtype of major depression that involves loss of interest or pleasure in almost all activities, and other symptoms, including early morning awakenings, worse depression in the morning, psychomotor agitation or retardation, loss of appetite or weight, and excessive guilt.

**Meninges.** Membranes that envelop the brain and spinal cord.

**Mental age (MA).** Scale unit indicating level of intelligence in relation to chronological age.

**Mental disorder.** Entire range of abnormal behavior patterns.

**Mental hygiene movement.** Movement that, as a method of treatment for the mentally ill, focused almost exclusively on the physical well-being of hospitalized mental patients.

**Mental illness.** Serious mental disorder.

**Mental retardation.** Significantly subaverage general intellectual functioning accompanied by significant limitations in adaptive functioning that is obvious during the developmental period.

**Mescaline.** Hallucinogenic drug derived from the peyote cactus.

**Mesmerism.** Theories of "animal magnetism" (hypnosis) formulated by Anton Mesmer.

**Methadone.** Synthetic narcotic related to heroin; used in treatment of heroin addiction because it replaces the craving for heroin and weans a person from heroin addiction.

**Microcephaly.** Form of mental retardation characterized by an abnormally small cranium and retarded development of the brain.

**Migraine.** Intensely painful, recurrent headache that typically involves only one side of the head and may be accompanied by nausea and other disturbances.

**Mild (disorder).** Disorder of a low order of severity.

**Milieu.** Immediate environment, physical or social or both.

**Milieu therapy.** General approach to therapy for hospitalized patients that focuses on making the hospital environment itself a part of the treatment program.

**Minnesota Multiphasic Personality Inventory (MMPI/MMPI-2/MMPI-A).** Widely used and empirically validated personality scales.

**Minor tranquilizers.** Antianxiety drugs, such as the benzodiazepines.

**Model.** Analogy that helps a scientist order findings and see important relationships among them.

**Modeling.** Form of learning in which a person learns by watching someone else (a model) perform a desired response.

**Moderate (disorder).** Disorder of an intermediate order of severity.

**Monozygotic twins.** Identical twins, developed from one fertilized egg.

**Mood-congruent.** Consistent with a person's mood.

**Mood disorders.** Disorders that have as their most prominent features disturbances of mood that are intense and persistent enough to be clearly maladaptive.

**Mood-incongruent.** Inconsistent with a person's mood.

**Moral management.** Wide-ranging method of treatment for the mentally ill that focuses on a patient's social, individual, and occupational needs.

**Moral therapy.** Therapy based on provision of kindness, understanding, and favorable environment; prevalent during early part of the nineteenth century.

**Morbid.** Unhealthy, pathological.

**Morphine.** Addictive drug derived from opium.

**Motivation.** Often used as a synonym for drive or activation; implies that an organism's actions are partly determined in direction and strength by its own inner nature.

**Motive.** Internal condition that directs action toward some goal; term usually used to include both the drive and the goal to which it is directed.

**Multi-infarct dementia.** See **Vascular dementia.**

**Multiple personality disorder.** See **Dissociative identity disorder.**

**Mutant gene.** Gene that has undergone some change in structure.

**Mutation.** Change in the composition of a gene, usually causing harmful or abnormal characteristics to appear in the offspring.

**Mutism.** Refusal or inability to speak.

**Nancy School, The.** Group of physicians in nineteenth-century Europe who accepted the view that hysteria was a sort of self-hypnosis.

**Narcissism.** Self-love.

**Narcissistic personality disorder.** Personality disorder characterized by grandiosity, an exaggerated sense of self-importance, preoccupation with being admired, and exploitation of others.

**Narcolepsy.** Disorder characterized by transient, compulsive states of sleepiness.

**Narcotic drugs.** Drugs, such as morphine, that lead to physiological dependence and increased tolerance.

**Natural killer cell.** White blood cell that destroys antigens by chemical dissolution.

**Necessary cause.** A condition that must exist for a disorder to occur.

**Need.** Biological or psychological condition whose gratification is necessary for the maintenance of homeostasis or for self-actualization.

**Negative automatic thoughts.** Thoughts that are just below the surface of awareness and that involve unpleasant pessimistic predictions.

**Negative cognitive triad.** Negative thoughts about the self, the world, and the future.

**Negative-symptom schizophrenia.** Schizophrenia characterized by an absence or deficit of normal or desirable behaviors, such as communicative speech and emotional reactivity.

**Negativism.** Form of aggressive withdrawal that involves refusing to cooperate or obey commands, or doing the exact opposite of what has been requested.

**Neologism.** New word; feature of language disturbance in schizophrenia.

**Neonate.** Newborn infant.

**Neoplasm.** Tumor.

**Nervous breakdown.** General term used to refer broadly to lowered integration and inability to deal adequately with one's life situation.

**Neurological examination.** Examination to determine the presence and extent of organic damage to the nervous system.

**Neurology.** Field concerned with the study of the brain and nervous system and disorders thereof.

**Neuron.** Individual nerve cell.

**Neurophysiology.** Branch of biology concerned with the functioning of nervous tissue and the nervous system.

**Neuropsychological assessment.** Use of psychological tests that measure a subject's cognitive, perceptual, and motor performance to determine the extent and locus of brain damage.

**Neuropsychological disorders.** Disorders that occur when there has been significant organic impairment or damage to a normal adolescent or adult brain.

**Neurosis.** Term historically used to characterize maladaptive behavior resulting from intrapsychic conflict and marked by prominent use of defense mechanisms.

**Neurosyphilis.** Syphilis affecting the central nervous system.

**Neurotic behavior.** Anxiety-driven, exaggerated use of avoidance behaviors and defense mechanisms.

**Neuroticism.** Personality pattern including anxiety, angry hostility, depression, self-consciousness, impulsiveness, and vulnerability.

**Neurotransmitters.** Chemical substances that transmit nerve impulses from one neuron to another.

**Nicotine.** Addictive akaloid that is the chief active ingredient in tobacco.

**Night hospital.** Mental hospital in which an individual may receive treatment during all or part of the night while carrying on his or her usual occupation in the daytime.

**Nihilistic delusion.** Fixed belief that everything is unreal.

**Nondirective therapy.** Approach to psychotherapy in which a therapist refrains from advice or direction of the therapy. See also **Client-centered psychotherapy.**

**Norepinephrine.** Catecholamine neurotransmitter substance.

**Norm.** Standard based on the measurement of a large group of people; used for comparing the scores of an individual with those of others in a defined group.

**Normal.** Conforming to the usual or norm; healthy.

**Normal distribution.** Tendency for most members of a population to cluster around a central point or average with respect to a given trait, with the rest spreading out to the two extremes.

**NREM sleep.** Stages of sleep not characterized by the rapid eye movements that accompany dreaming.

**Nuclear magnetic resonance imaging (MRI).** Internal scanning technique involving measurement of variations in magnetic fields that allows visualization of the anatomical features of internal organs, including the brain.

**Objective tests.** Structured tests, such as a questionnaires, self-inventories, or rating scales, used in psychological assessment.

**Object-relations.** In psychoanalytic theory, a viewpoint that emphasizes interpersonal relationships by focusing on internalized "objects" that can have varying conflicting properties.

**Observational method.** Systematic technique by which observers are trained to watch and record behavior without bias.

**Obsessions.** Recurrent and persistent thoughts, impulses, or images that a person experiences as intrusive and inappropriate but has difficulty suppressing.

**Obsessive-compulsive disorder.** Anxiety disorder characterized by the persistent intrusion of unwanted and intrusive thoughts or distressing images; these are usually accompanied by compulsive behaviors designed to neutralize the obsessive thoughts or images.

**Obsessive-compulsive personality disorder.** Personality disorder characterized by excessive concern with maintaining order, control, and adherence to rules.

**Occipital lobe.** Portion of cerebrum concerned chiefly with visual function.

**Oedipus complex.** Desire for sexual relations with parent of opposite sex, specifically that of a boy for his mother.

**Olfactory hallucinations.** Hallucinations involving the sense of smell.

**Operant conditioning.** Form of learning in which a particular response is reinforced and becomes more likely to occur.

**Operational definition.** Defining a concept on the basis of a set of operations that can be observed and measured.

**Opium.** Narcotic drug that leads to physiological dependence and the development of tolerance; derivatives are morphine, heroin, and codeine.

**Oral stage.** First stage of psychosexual development in Freudian theory, in which mouth or oral activities are the primary source of pleasure.

**Organic mental disorders.** Mental disorders associated with organic brain pathology. Called *brain disorders* in DSM-IV.

**Organic viewpoint.** Concept that all mental disorders have an organic basis. See also **Biological viewpoint.**

**Orgasm.** Phase of the human sexual response during which there is a release of sexual tension and a peaking of sexual pleasure.

**Outcome research.** Studies of effectiveness of treatment.

**Outpatient.** Ambulatory client who visits a hospital or clinic for examination and treatment, as distinct from a hospitalized client.

**Ovaries.** Female gonads.

**Overanxious disorder.** Disorder of childhood characterized by excessive worry and persistent fears unrelated to any specific event; often includes somatic and sleeping problems.

**Overcompensation.** Type of ego-defense mechanism in which an undesirable trait is covered up by exaggerating a desirable trait.

**Overloading.** Subjecting an organism to excessive stress, e.g., forcing the organism to handle or "process" an excessive amount of information.

**Overprotection.** Shielding a child to the extent that he or she becomes too dependent on the parent.

**Overt behavior.** Activities that can be observed by an outsider.

**Ovum.** Female gamete or germ cell.

**Pain disorder.** A somatoform condition characterized by the report of pain of sufficient duration and severity to cause significant life disruption in the absence of medical pathology that would explain it.

**Panic.** A basic emotion involving the activation of the "fight or flight" response.

**Panic disorder.** Type of anxiety disorder involving recurring and unexpected panic attacks.

**Paradigm.** Model or pattern; in research, a basic design specifying concepts considered legitimate and procedures to be used in the collection and interpretation of data.

**Paranoia.** Symptoms of delusions and impaired contact with reality but without the severe personality disorganization characteristic of schizophrenia.

**Paranoid personality disorder.** Personality disorder characterized by pervasive suspiciousness and distrust of others.

**Paraphilias.** Sexual behavior patterns in which unusual objects, rituals, or situations are required for full sexual satisfaction.

**Paraprofessional.** Person who has been trained in mental health services, but not at the professional level.

**Parasympathetic nervous system.** Division of the autonomic nervous system that controls most of the basic metabolic functions essential for life.

**Paresis.** See **General paresis.**

**Paresthesia.** Exceptional sensations, such as tingling.

**Parkinson's disease.** Progressive disease characterized by a masklike, expressionless face and various neurological symptoms, such as tremors.

**Passive-aggressive personality disorder.** Provisional personality disorder in DSM-IV characterized by a pattern of passive resistance to demands in social or occupational situations, which may take such forms as procrastinating, "forgetting," or sulking.

**Pathogenic.** Pertaining to conditions that lead to pathology.

**Pathological gambling.** Addictive disorder in which gambling disrupts a person's life.

**Pathology.** Abnormal physical or mental condition.

**PCP.** Phencyclidine; developed as a tranquilizer but not marketed because of its unpredictability. Known on the street as "angel dust," this drug produces stuporous conditions and, at times, prolonged comas or psychoses.

**Pedophilia.** Sexual variant in which an adult's preferred or exclusive sexual partner is a prepubertal child.

**Perception.** Interpretation of sensory input.

**Perceptual filtering.** Processes involved in selective attention to aspects of the great mass of incoming stimuli that continually impinge on an organism.

**Performance test.** Test in which perceptual-motor rather than verbal content is emphasized.

**Peripheral nervous system.** Nerve fibers passing between the central nervous system and the sense organs, muscles, and glands.

**Perseveration.** Persistent continuation of a line of thought or activity once it is under way. Clinically inappropriate repetition.

**Personality.** Unique pattern of traits that characterizes an individual.

**Personality disorders.** Conditions involving long-standing patterns of inflexible and maladaptive behavior serious enough to interfere with social and/or occupational functioning.

**Personality profile.** Graphic summary from several tests or subtests of the same test battery or scale that shows the personality configuration of an individual or group of individuals.

**Person-centered therapy.** See **Client-centered therapy.**

**Pervasive developmental disorder.** Severe disorder of childhood marked by deficits in language, perceptual, and motor development; defective reality testing; and inability to function in social situations.

**Pessimistic attributional style.** Cognitive style involving a tendency to make internal, stable, and global attributions for negative life events.

**PET scan.** See **Positron emission tomography.**

**Phagocyte.** Circulating white blood cell that binds to antigens and partially destroys them by engulfment.

**Phallic stage.** In psychoanalytic theory, the stage of psychosexual development during which genital exploration and manipulation occur.

**Pharmacology.** The science of drugs.

**Pharmacotherapy.** Treatment by means of drugs.

**Phenomenological.** Referring to the immediate perceiving and experiencing of an individual.

**Phenotype.** The observed structural and functional characteristics of an individual that result from an interaction between the genotype and the environment.

**Phenylketonuria (PKU).** Type of mental retardation resulting from a metabolic deficiency.

**Phobia.** Persistent and disproportionate fear of some specific object or situation that presents little or no actual danger to a person.

**Physiological dependence.** Type of drug dependence involving withdrawal symptoms when drug is discontinued.

**Pick's disease.** Form of presenile dementia.

**Pineal gland.** Small gland at the base of the brain that helps regulate the body's biological clock and may also pace sexual development.

**Pituitary gland.** Endocrine gland associated with many regulatory functions.

**Placebo effect.** Positive effect experienced after an inactive treatment is administered in such a way that a person thinks he or she is receiving an active treatment.

**Play therapy.** Use of play activities in psychotherapy with children.

**Pleasure principle.** In psychoanalysis, the demand that an instinctual need be immediately gratified, regardless of reality.

**Polygenic.** Caused by the action of many genes together in an additive or interactive fashion.

**Poor premorbid schizophrenia.** See **Process schizophrenia.**

**Positive reinforcer.** Reinforcer that increases the probability of recurrence of a given response.

**Positive-symptom schizophrenia.** Schizophrenic disorders characterized by elements added to normal behavior, such as delusions and hallucinations.

**Positron emission tomography (PET scan).** Scanning technique that measures the level of metabolic activity in particular regions of the body.

**Posthypnotic amnesia.** Subject's lack of memory for the period during which he or she was hypnotized.

**Posthypnotic suggestion.** Suggestion given during hypnosis to be carried out by a subject after he or she is brought out of hypnosis.

**Postpartum depression.** Depression occurring after childbirth.

**Posttraumatic stress disorder (PTSD).** Disorder that occurs following an extreme traumatic stress or in which a person shows symptoms of reexperiencing the event of avoiding reminders of the trauma, and of persistent symptoms of increased arousal.

**Predisposition.** Increased likelihood that a person will develop certain symptoms under given stress conditions.

**Prefrontal lobotomy.** Surgical procedure used before the advent of antipsychotic drugs in which frontal lobes of the brain were severed from the deeper centers underlying them, resulting in permanent brain damage.

**Prejudice.** Emotionally toned conception favorable or unfavorable to some person, group, or idea—typically in the absence of sound evidence.

**Premature ejaculation.** Persistent and recurrent onset of orgasm and ejaculation with minimal sexual stimulation.

**Prematurity.** Birth of an infant before the end of a normal period of pregnancy.

**Premorbid.** Existing before the onset of mental disorder.

**Prenatal.** Before birth.

**Presenile dementia.** Senile brain deterioration before old age.

**Prevalence.** Term that refers to the rate of active cases of something under study (in this case, a disorder) that can be identified at a given period in time.

**Primary prevention.** Preventive efforts aimed at reducing the possibility of disease or disorder and fostering positive health.

**Primary process thinking.** Gratification of an id demand by means of imagery or fantasy; a psychoanalytic concept.

**Primary reaction tendencies.** Constitutional tendencies apparent in infancy, such as sensitivity and activity level.

**Proband.** In a genetic study, the original individual who evidences the trait in which the investigator is interested. Same as **index case.**

**Problem checklist.** Inventory used in behavioral assessment to determine an individual's fears, moods, and other problems.

**Problem drinker.** Behavioral term referring to one who has serious problems associated with drinking.

**Process schizophrenia.** Schizophrenic pattern—marked by seclusiveness, gradual lack of interest in the surrounding world, diminished emotional responsivity, and mildly inappropriate responses—that develops gradually and tends to be long-lasting; alternatively known as *poor premorbid schizophrenia* and *chronic schizophrenia.*

**Prognosis.** Prediction as to the probable course and outcome of a disorder.

**Projection.** Ego-defense mechanism in which a person attributes unacceptable desires and impulses to others.

**Projective tests.** Techniques that use neutral or ambiguous stimuli that a subject is encouraged to interpret and from which the subject's personality characteristics can be analyzed.

**Prospective research.** Research that focuses, before the fact, on people who have a higher-than-average likelihood of becoming psychologically disordered, following them over time.

**Protective factors.** Influences that modify a person's response to an environmental stressor, making it less likely that the person will experience the adverse effects of the stressor.

**Prototypal approach.** Approach to classifying abnormal behavior that assumes the existence of prototypes of behavior disorders that, rather than being mutually exclusive, may blend into others with which they share many characteristics.

**Psilocybin.** Hallucinogenic drug derived from a mushroom.

**Psychedelic drugs.** Drugs such as LSD that often produce hallucinations.

**Psychiatric nursing.** Field of nursing primarily concerned with mental disorders.

**Psychiatric social worker.** Professional having graduate training in social work with psychiatric specialization, typically involving a master's degree.

**Psychiatrist.** Medical doctor who specializes in the diagnosis and treatment of mental disorders.

**Psychiatry.** Field of medicine concerned with understanding, assessing, treating, and preventing mental disorders.

**Psychic trauma.** Any aversive experience that inflicts serious psychological damage on a person.

**Psychoactive drugs.** Drugs that affect mental functioning.

**Psychoactive substance abuse.** Pathological use of a substance resulting in potentially hazardous behavior or in continued use despite a persistent social, psychological, occupational, or health problem.

**Psychoactive substance dependence.** Use of a psychoactive substance to the point that one has a physiological need for it.

**Psychoanalysis.** Theoretical model and therapeutic approach developed by Freud.

**Psychoanalytic perspective.** Theory of psychopathology, initially developed by Freud, that emphasizes the inner dynamics of unconscious motives.

**Psychodrama.** Psychotherapeutic technique in which the acting of various roles is a cardinal part.

**Psychodynamic perspectives.** Theories of psychopathology based on Freud's theories but modified and revised.

**Psychodynamic therapy.** Treatment focusing on individual personality dynamics from a psychodynamic perspective.

**Psychogenic.** Of psychological origin: originating in the psychological functioning of an individual.

**Psychogenic amnesia.** Amnesia of psychological origin, common in initial reactions to intolerable traumatic experiences.

**Psychohistory.** A field of study analyzing history according to psychoanalytic principles.

**Psychological autopsy.** Analytical procedure used to determine whether or not death was self-inflicted.

**Psychological need.** Need emerging out of environmental interactions, e.g., the need for social approval.

**Psychological screening.** Use of psychological procedures or tests to detect psychological problems among applicants in preemployment evaluations.

**Psychological test.** Standardized procedure designed to measure a subject's performance on a specified task.

**Psychomotor.** Involving both psychological and physical activity.

**Psychomotor retardation.** Slowing down of psychological and motor functions.

**Psychoneuroimmunology.** Field whose focus is understanding the psychological influences on the nervous system's control of immune responsiveness.

**Psychopathology.** Abnormal behavior.

**Psychopathy.** A condition involving the features of antisocial personality disorder plus the traits of lack of empathy, inflated self-appraisal, and glib and superficial charm.

**Psychopharmacological drugs.** Drugs used in treatment of mental disorders.

**Psychophysiologic (psychosomatic) disorders.** Physical disorders in which psychological factors are believed to play a major causative role.

**Psychosexual development.** Freudian view of development as involving a succession of stages, each characterized by a dominant mode of achieving libidinal pleasure.

**Psychosexual stages of development.** According to Freudian theory, there are five stages of psychosexual development, each characterized by a dominant mode of achieving sexual pleasure: the oral stage, the anal stage, the phallic stage, the latency stage, and the genital stage.

**Psychosis.** Serious mental disorder involving a loss of contact with reality, as when hallucinations or delusions are present.

**Psychosocial deprivation.** Lack of needed stimulation and interaction during early life.

**Psychosocial viewpoints.** Approaches to understanding behavior disorders that emphasize the importance of early experience and an awareness of social influences and psychological processes within an individual.

**Psychosurgery.** Brain surgery used in the treatment of functional mental disorders.

**Psychotherapy.** Treatment of mental disorders by psychological methods.

**Psychotropic drugs.** Drugs whose main effects are mental or behavioral in nature.

**Q-sort.** Personality inventory in which a subject, or a clinician, sorts a number of statements into piles according to their applicability to the subject.

**Racism.** Prejudice and discrimination directed toward individuals or groups because of their racial background.

**Random sample.** Sample drawn in such a way that each member of a population has an equal chance of being selected; hopefully representative of the population from which it is drawn.

**Rape.** Sexual activity that occurs under actual or threatened forcible coercion of one person by another.

**Rapid cycling.** A pattern of bipolar disorder involving at least four manic or depressive episodes per year.

**Rapport.** Interpersonal relationship characterized by a spirit of cooperation, confidence, and harmony.

**Rating scales.** Devices for evaluating oneself or someone else with regard to specific traits.

**Rational-emotive therapy.** Form of psychotherapy focusing on cognitive and emotional restructuring to foster adaptive behavior.

**Rationalization.** Ego-defense mechanism in which a person devises "good" reasons to justify his or her actions.

**Reaction formation.** Ego-defense mechanism in which a person's conscious attitudes and overt behavior are opposite to repressed unconscious wishes.

**Reactive schizophrenia.** Schizophrenia pattern—marked by confusion and intense emotional turmoil—that normally develops suddenly and has identifiable precipitating stressors; alternatively known as *good premorbid schizophrenia* and *acute schizophrenia*.

**Reality principle.** Awareness of the demands of the environment and adjustment of behavior to meet these demands.

**Reality testing.** Behavior aimed at testing or exploring the nature of a person's social and physical environment; often used more specifically to refer to the testing of the limits of permissiveness of the social environment.

**Recessive gene.** Gene that is effective only when paired with an identical gene.

**Recidivism.** Shift back to one's original behavior (often delinquent or criminal) after a period of treatment or rehabilitation.

**Recompensation.** Increase in integration or inner organization. Opposite of ***decompensation.***

**Recurrence.** A new occurrence of a disorder after a significant period of time.

**Recurrent.** Used to describe a disorder pattern that tends to come and go.

**Referral.** Sending or recommending an individual and/or family for psychological assessment and/or treatment.

**Regression.** Ego-defense mechanism in which a person retreats to the use of less mature responses in attempting to cope with stress and maintain ego integrity.

**Rehabilitation.** Use of reeducation rather than punishment to overcome behavioral deficits.

**Reinforcement.** In classical conditioning, the process of following the conditioned stimulus with the unconditioned stimulus; in operant conditioning, the rewarding of desired responses.

**Relapse.** The return of the symptoms of a disorder after a fairly short period of time.

**Reliability.** Degree to which a test or measuring device produces the same result each time it is used to measure the same thing.

**Remission.** Marked improvement or recovery appearing in the course of a mental illness; may or may not be permanent.

**REM sleep.** Stage of sleep involving rapid eye movements (REM), associated with dreaming.

**Representative sample.** Small group selected in such a way as to be representative of the larger group from which it is drawn.

**Repression.** Ego-defense mechanism by means of which dangerous desires and intolerable memories are kept out of consciousness.

**Resilience.** The ability to overcome challenging or threatening circumstances.

**Resistance.** In psychodynamic treatment, the client's avoidance of certain topics as a means of preventing threatening material from entering awareness.

**Resistance to extinction.** Tendency of a conditioned response to persist despite lack of reinforcement.

**Resolution.** Final phase of the human sexual response, during which a person has a sense of relaxation and well-being.

**Response shaping.** Positive reinforcement technique used in therapy to establish a response not initially in a person's behavioral repertoire.

**Reticular activating system (RAS).** Fibers going from the reticular formation to higher brain centers and presumably functioning as a general arousal system.

**Reticular formation.** Neural nuclei and fibers in the brain stem that apparently play an important role in arousing and alerting an organism and in controlling attention.

**Retrograde amnesia.** Loss of memory for events during a circumscribed period prior to brain injury or damage.

**Retrospective research.** Research that looks backward from the present.

**Retrospective study.** Research approach that attempts to retrace earlier events in the life of a subject.

**Rigidity.** Tendency to follow established coping patterns, with failure to see alternatives or extreme difficulty in changing one's established patterns.

**Ritalin.** Central nervous system stimulant often used to treat attention-deficit hyperactivity disorder in children.

**Role playing.** Form of assessment or psychotherapy in which a person acts out a social role other than his or her own or tries out a new role.

**Rorschach test.** Series of inkblots to which a subject responds with associations that come to mind. Analysis of these responses enables a clinician to infer personality characteristics.

**Sadism.** Sexual variant in which sexual gratification is obtained by inflicting pain or humiliation on a sexual partner.

**Sample.** Group on which measurements are taken; should normally be representative of the population about which an inference is to be made.

**Sampling.** The process of selecting a representative subgroup from a defined population of interest.

**Scapegoating.** Displacement of aggression onto some object, person, or group other than the source of frustration.

**Schedule of reinforcement.** Program of rewards for requisite behavior.

**Schema.** An organized representation of prior knowledge about a concept or about some stimulus that helps guide a person's processing of current information.

**Schizoaffective disorder.** Major mood disorder in which a person also has at least two major symptoms of schizophrenia, such as hallucinations and delusions.

**Schizoid personality disorder.** Personality disorder characterized by an inability to form social relationships or express feelings, a lack of social skills, and indifference.

**Schizophrenia.** Psychosis characterized by the breakdown of integrated personality functioning, withdrawal from reality, emotional blunting and distortion, and disturbances in thought and behavior.

**Schizophrenia, catatonic type.** Type of schizophrenia in which the central feature is pronounced motor symptoms, either of an excited or stuporous type, which sometimes make it difficult to differentiate this condition from a psychotic mood disorder.

**Schizophrenia, disorganized type.** Type of schizophrenia that usually begins at an earlier age and represents a more severe disintegration of the personality than in the other types of schizophrenia.

**Schizophrenia, paranoid type.** Type of schizophrenia in which a person is increasingly suspicious, has severe difficulties in interpersonal relationships, and experiences absurd, illogical, and often changing delusions.

**Schizophrenia, residual type.** Diagnostic category used for people regarded as having recovered from a schizophrenic episode but still manifesting some signs of their past disorder.

**Schizophrenia, undifferentiated type.** Type of schizophrenia in which a person meets the usual criteria for being schizophrenic—including (in varying combinations) delusions, hallucinations, thought disorder, and bizarre behavior—but does not clearly fit into one of the other types because of a mixed symptom picture.

**Schizophreniform disorder.** Category of schizophrenic disorder, usually in an undifferentiated form, of less than six months duration.

**Schizophrenogenic.** Schizophrenia-causing.

**Schizotypal personality disorder.** Personality disorder in which social withdrawal, cognitive distortions, and eccentricity of thought and perception are distinguishing traits.

**Seasonal affective disorder.** Mood disorder involving at least two episodes of depression in the past two years occuring at the same time of year (most commonly fall or winter), with remission also occurring at the same time of year (most commonly spring).

**Secondary gain.** Indirect benefit from psychopathological symptoms.

**Secondary prevention.** Prevention techniques that typically involve emergency or crisis intervention, with efforts focused on reducing the impact, duration, or spread of a problem.

**Secondary process thinking.** Reality-oriented rational processes of the ego.

**Secondary reinforcer.** Reinforcement provided by a stimulus that has gained reward value by being associated with a primary reinforcing stimulus.

**Sedative.** Drug used to reduce tension and induce relaxation and sleep.

**Selective vigilance.** Tuning of attentional and perceptual processes toward stimuli relevant or central to goal-directed behavior, with decreased sensitivity to stimuli irrelevant or peripheral to this purpose.

**Self (ego).** Integrating core of a personality that mediates between needs and reality.

**Self-acceptance.** Being satisfied with one's attributes and qualities while remaining aware of one's limitations.

**Self-actualizing.** Achieving one's full potentialities as a human being.

**Self-concept.** A person's sense of his or her own identity, worth, capabilities, and limitations.

**Self-esteem.** Feeling of personal worth.

**Self-evaluation.** Way in which an individual views the self, in terms of worth, adequacy, etc.

**Self-ideal (ego-ideal).** Person or "self" a person thinks he or she could and should be.

**Self-identity.** Individual's delineation and awareness of his or her continuing identity as a person.

**Self-instructional training.** Cognitive-behavioral method aimed at teaching a person to alter his or her covert behavior.

**Self-monitoring.** Observing and recording one's own behavior, thoughts, and feelings.

**Self-reinforcement.** Reward of self for desired or appropriate behavior.

**Self-report inventory.** Procedure in which a subject is asked to respond to statements in terms of their applicability to him or her.

**Self-schema.** Our concept of what we are, what we might become, and what is important to us.

**Self-statements.** A person's implicit verbalizations of what he or she is experiencing.

**Self-system.** According to Sullivan's interpersonal theory, a system that protects a person from anxiety by controlling awareness—the person simply does not attend to elements of experience that cause anxiety and may even block out of consciousness especially severe anxiety-arousing experiences.

**Senile.** Pertaining to old age.

**Senile dementia.** Deteriorative brain changes due to aging.

**Sensate focus learning.** Training to derive pleasure from touching one's partner and being touched by him or her; used in sexual therapy to enhance sexual feelings and help overcome sexual dysfunction.

**Sensory deprivation.** Restriction of sensory stimulation below the level required for normal functioning of the central nervous system.

**Sentence-completion test.** Projective technique utilizing incomplete sentences that a subject is to complete, analysis of which enables a clinician to infer personality dynamics.

**Separation anxiety disorder.** Childhood disorder characterized by unrealistic fears, oversensitivity, self-consciousness, nightmares, and chronic anxiety.

**Separation-individuation.** According to Mahler, a developmental phase in which a child gains an internal representation of self as distinct from representations of other objects.

**Sequelae.** Symptoms remaining as the aftermath of a disorder.

**Severe (disorder).** Disorder of a high degree of seriousness.

**Severe major depressive episode with psychotic features.** Major depression involving loss of contact with reality, often in the form of delusions or hallucinations.

**Sex chromosomes.** Pair of chromosomes inherited by an individual that determine sex and certain other characteristics.

**Sexual abuse.** Sexual contact that involves pressured or forced sexual contact.

**Sexual aversion disorder.** Sexual dysfunction in which a person shows extreme aversion to, and avoidance of, all genital sexual contact with a partner.

**Sexual dysfunction.** Impairment either in the desire for sexual gratification or in the ability to achieve it.

**Shaping.** Form of instrumental conditioning; at first, all responses resembling the desired one are reinforced, then only the closest approximations, until finally the desired response is attained.

**Shared psychotic disorder.** Psychosis in which two or more people develop persistent, interlocking delusional ideas. Also known as *folie à deux.*

**Sheltered workshops.** Workshops where mentally retarded or otherwise handicapped persons can engage in constructive work in the community.

**Short-term crisis therapy.** Brief therapy that focuses on the immediate problem—personal or family problems of an emotional nature—with which an individual or family is having difficulty.

**Siblings.** Offspring of the same parents.

**Sick role.** Protected role provided by society via the medical model for a person suffering from severe physical or mental disorder.

**Sign.** Observable manifestation of a physical or mental disorder.

**Significant others.** In interpersonal theory, parents or others on whom an infant is dependent for meeting all physical and psychological needs.

**Simple phobia.** See **Specific phobia.**

**Simple tension headaches.** Commonplace headaches in which stress leads to contraction of the muscles surrounding the skull; these contractions, in turn, result in vascular constrictions that cause headache pain.

**Situational test.** Test that measures performance in a simulated life situation.

**Sleepwalking disorder.** Disorder of childhood that involves repeated episodes in which a child leaves his or her bed and walks around without being conscious of the experience or remembering it later. Also known as *somnambulism.*

**Social exchange view.** Model of interpersonal relationships based on the premise that such relationships are formed for mutual need gratification.

**Social introversion.** Trait characterized by shy, withdrawn, and inhibited behavior.

**Socialization.** Process by which a child acquires the values and impulse controls deemed appropriate by his or her culture.

**Social-learning programs.** Behavioral programs using learning techniques, especially token economies, to help patients assume more responsibility for their own behavior.

**Social norms.** Group standards concerning behaviors viewed as acceptable or unacceptable.

**Social pathology.** Abnormal patterns of social organization, attitudes, or behavior; undesirable social conditions that tend to produce individual pathology.

**Social phobia.** Persistent and disproportionate fear of one or more situations in which one is exposed to focused scrutiny by others and the corollary fear that one may do something embarrassing or humiliating.

**Social role.** Behavior expected of a person occupying a given position in a group.

**"Social" self.** Facade a person displays to others as contrasted with the private self.

**Social work.** Applied offshoot of sociology concerned with the analysis of social environments and providing services that assist the adjustment of a client in both family and community settings.

**Social worker.** Person in a mental health field with a master's degree in social work (MSW) plus supervised training in clinical or social service agencies.

**Sociocultural viewpoint.** Pertaining to broad social conditions that influence the development and/or behavior of individuals and groups.

**Socioeconomic status.** Position on social and economic scale in community; determined largely by income and occupational level.

**Sociogenic.** Having its roots in sociocultural conditions.

**Sociopathic personality.** See **Psychopathy.**

**Sodium pentothal.** Barbiturate drug sometimes used in psychotherapy to produce a state of relaxation and suggestibility.

**Somatic.** Pertaining to the body.

**Somatic weakness.** Special vulnerability of given organ systems to stress.

**Somatization disorder.** Somatoform disorder beginning before age 30 and continuing for many years, characterized by multiple complaints of physical ailments that are inadequately explained by findings of physical illness or injury.

**Somatoform disorders.** Conditions involving physical complaints or disabilities occurring in the absence of any physical pathology that could account for them.

**Somnambulism.** See **Sleepwalking disorder.**

**Spasm.** Intense, involuntary, usually painful contraction of a muscle or group of muscles.

**Spasticity.** Marked hypertonicity or continual overcontraction of muscles, causing stiffness, awkwardness, and motor incoordination.

**Specific learning disorders.** Developmental disorders involving deficits in specific academic skills.

**Specific phobia.** A persistent and disproportionate fear of something, such as an animal (snakes, insects) or some aspect of the environment (high places, water).

**Sperm.** Male gamete or germ cell.

**Split-brain research.** Research associated with split-brain surgery, which cuts off the transmission of information from one cerebral hemisphere to the other, through severing the corpus callosum.

**Spontaneous recovery.** The return of a learned response at some time after extinction has occurred.

**Stage of exhaustion.** Third and final stage in the general adaptation syndrome, in which an organism is no longer able to resist continuing stress; may result in death.

**Stage of resistance.** Second stage of the general adaptation syndrome.

**Standardization.** Procedure for establishing the expected performance range on a test.

**Stanford-Binet.** Standardized intelligence test for children.

**Startle reaction.** Sudden involuntary motor reaction to intense unexpected stimuli; may result from mild stimuli if a person is hypersensitive.

**Statutory rape.** Sexual intercourse with a minor.

**Steady states (homeostasis).** Tendency of an organism to maintain conditions making possible a constant level of physiological functioning.

**Stereotype.** Generalized notion of how people of a given race, religion, or other group will appear, think, feel, or act.

**Stereotypy.** Persistent and inappropriate repetition of phrases, gestures, or acts.

**Stimulants.** Drugs that tend to increase feelings of alertness, reduce feelings of fatigue, and enable a person to stay awake over sustained periods of time.

**Stimulus generalization.** Spread of a conditioned response to some stimulus similar to, but not identical with, the conditioned stimulus.

**Stress.** Internal responses caused by the application of a stressor.

**Stress-inoculation therapy.** Type of self-instructional training focused on altering self-statements that a person habitually makes in order to restructure his or her characteristic approach to stress-producing situations.

**Stress-inoculation training.** Cognitive-behavioral technique that prepares people to tolerate an anticipated threat by the use of positive self-statements.

**Stressor.** Any adjustive demand that requires coping behavior on the part of an individual or group.

**Stress tolerance.** Nature, degree, and duration of stress that a person can tolerate without undergoing serious personality decompensation.

**Stroke.** See **Cerebrovascular accident.**

**Structural family therapy.** Treatment of an entire family by analysis of interaction among family members.

**Stupor.** Condition of lethargy and unresponsiveness, with partial or complete unconsciousness.

**St. Vitus's dance.** Hysterical chorea of common occurrence during the Middle Ages.

**Sublimation.** Ego-defense mechanism by means of which frustrated sexual energy is partially channeled into substitutive activities.

**Substance abuse.** Maladaptive pattern of substance use manifested by recurrent and significant adverse consequences related to the use of the substance.

**Substance dependence.** Severe form of substance use disorder involving physiological dependence on the substance, tolerance, withdrawal, and compulsive drug taking.

**Substance-related disorders.** Patterns of maladaptive behavior centered on the regular use of a substance, such as drugs or alcohol.

**Substitution.** Acceptance of substitute goals or satisfactions in place of those originally sought after or desired.

**Successive approximation.** See **Shaping.**

**Sufficient cause.** A condition that guarantees the occurence of a disorder.

**Suicide.** Taking one's own life.

**Suicidology.** Study of the causes and prevention of suicide.

**Superego.** Conscience; ethical or moral dimensions (attitudes) of personality.

**Suppression.** Conscious forcing of desires or thoughts out of consciousness; conscious inhibition of desires or impulses.

**Surrogate.** Substitute for another person, as parent or mate.

**Symbol.** Image, word, object, or activity that is used to represent something else.

**Symbolism.** Representation of one idea or object by another.

**Sympathetic division.** Division of the autonomic nervous system that is active in emergency conditions of extreme cold, violent effort, and emotions.

**Symptom.** Manifestation of a physical or mental disorder as experienced or reported by the patient.

**Syndrome.** Group or pattern of symptoms that occur together in a disorder and represent the typical picture of the disorder.

**System.** Assemblage of interdependent parts, living or nonliving.

**Systematic desensitization.** Behavior therapy technique for eliminating maladaptive anxiety responses by teaching a person to relax or behave in some other way that is inconsistent with anxiety while in the presence of the anxiety-producing stimulus.

**Tachycardia.** Rapid heartbeat.

**Tactual hallucinations.** Hallucinations involving the sense of touch.

**Tarantism.** Dancing mania that occurred in Italy and later spread to Germany and the rest of Europe, where it was known as St. Vitus's dance.

**Tarasoff decision.** Ruling by a California court (1974) that a therapist has a duty to warn a prospective victim threatened by a client in therapy.

**Tardive dyskinesia.** Neurological disorder resulting from excessive use of phenothiazines. The drug side effects can occur months to years after treatment has been initiated or has stopped. The symptoms involve involuntary movements of the tongue, lips, jaw, and extremities.

**Task-oriented response.** Behavior directed primarily at dealing with the requirements of a stressor rather than at defending the self.

**Tay-Sachs disease.** Genetic disorder of lipoid metabolism usually resulting in death by age three.

**T-cell.** Generic type of lymphocyte crucial in immune functioning and having several subtypes that support and regulate the entire immune reaction.

**Telepathy.** Communication from one person to another without use of any known sense organs.

**Temperament.** Pattern of emotional and arousal responses that are considered to be primarily hereditary or constitutional.

**Temporal lobe.** Portion of cerebrum located in front of the occipital lobe and separated from frontal and parietal lobes by the fissure of Sylvius.

**Tension.** Condition arising from the mobilization of psychobiological resources to meet a threat; physically, involves an increase in muscle tone and other emergency changes; psychologically, is characterized by feelings of strain, uneasiness, and anxiety.

**Tertiary prevention.** Preventive techniques focusing on reducing long-term consequences of disorders or serious problems.

**Testes.** Male reproductive glands or gonads.

**Testosterone.** Male sex hormone.

**Test reliability.** Consistency with which a test measures a given trait on repeated administrations of the test to given subjects.

**Test validity.** Degree to which a test actually measures what it was designed to measure.

**Thematic Apperception Test (TAT).** Psychological test composed of a series of pictures about which a subject makes up a story. Analysis of the story gives a clinician clues about the person's conflicts, traits, personality dynamics, etc.

**Therapeutic.** Pertaining to treatment or healing.

**Therapeutic community.** Hospital environment used for therapeutic purposes.

**Therapy.** Treatment; application of various treatment techniques.

**Thyroid.** Endocrine gland located in the neck that influences body metabolism, rate of physical growth, and development of intelligence.

**Thyroxin.** Hormone secreted by the thyroid glands.

**Tic.** Persistent, intermittent muscle twitch or spasm, often of the facial muscles.

**Token economy.** Reinforcement technique often used in hospital or institutional settings in which patients are rewarded for socially constructive behavior with tokens that can then be exchanged for desired objects or activities.

**Tolerance.** Physiological condition in which an increased dosage of an addictive drug is needed to obtain effects previously produced by a smaller dose.

**Tourette's syndrome.** Extreme tic disorder in which an affected person has extensive uncontrollable motor and verbal mannerisms.

**Toxic.** Poisonous.

**Toxicity.** Poisonous nature of a substance.

**Trait.** Characteristic of a person that can be observed or measured.

**Trance.** Sleeplike state in which the range of consciousness is limited and voluntary activities are suspended; a deep hypnotic state.

**Tranquilizers.** Drugs used for reduction of psychotic symptoms and/or reduction of anxiety and tension. See also **Major tranquilizers** and **Minor tranquilizers.**

**Transference.** In psychodynamic therapy, process whereby a client projects attitudes and emotions applicable to another significant person onto the therapist.

**Transsexualism.** Identification of oneself with members of the opposite sex, as opposed to acceptance of one's anatomical sexual identity. Gender identity disorder in adults.

**Transvestic fetishism.** Achievement of sexual arousal and satisfaction by dressing as a member of the opposite sex.

**Trauma.** Severe psychological or physiological stressor.

**Traumatic.** Pertaining to a wound or injury, or to psychic shock.

**Traumatic childhood abuse.** Mistreatment in childhood severe enough to cause psychological damage.

**Treatment contract.** Explicit arrangement between a therapist and a client designed to bring about specific behavioral changes.

**Tremor.** Repeated fine spastic movement.

**Type A behavior pattern.** Complex set of behaviors—involving excessive competitive drive in the absence of well-defined goals, impatience or time urgency, and hostility—that may be observed in some people under stressful or challenging circumstances.

**Unconscious.** As used by Freud, psychological material that has been repressed. Also, loss of consciousness; lack of awareness.

**Underarousal.** Inadequate physiological response to a given stimulus.

**Undoing.** Ego-defense mechanism by means of which a person performs activities designed to atone for his or her misdeeds, thereby, in a sense, "undoing" them.

**Unipolar disorder.** Severe mood disorder in which only depressive episodes occur, as opposed to bipolar disorder, in which both manic and depressive episodes occur.

**Vaginismus.** Involuntary spasm of the muscles at the entrance to the vagina that prevents penetration and sexual intercourse.

**Validity.** Extent to which a measuring instrument actually measures what it purports to measure.

**Variable.** Characteristic or property that may assume any one of a set of different qualities or quantities.

**Vascular dementia (VAD).** A brain disorder in which a series of cerebral infarcts (strokes) destroy neurons, leading to brain atrophy and behavioral impairments.

**Vasomotor.** Pertaining to the walls of the blood vessels.

**Vegetative.** Withdrawn or deteriorated to the point of leading a passive, vegetable-like existence.

**Verbal test.** Test in which a subject's ability to understand and use words and concepts is important in making the required responses.

**Vertigo.** Dizziness.

**Virilism.** Accentuation of masculine secondary sex characteristsics, especially in a woman or young boy, caused by hormonal imbalance.

**Viscera.** Internal organs.

**Voyeurism.** Achievement of sexual pleasure through clandestine "peeping," usually watching other people disrobe and/or engage in sexual activities.

**Vulnerabilities.** Factors rendering a person susceptible to behaving abnormally.

**Wechsler Intelligence Scale for Children (WISC).** Standardized intelligence test for children.

**Withdrawal.** Intellectual, emotional, or physical retreat.

**Withdrawal symptoms.** Physical symptoms such as sweating, tremors, and tension that accompany abstinence from an addictive drug.

**Word salad.** Jumbled or incoherent use of words by psychotic or disoriented individuals.

**X chromosome.** Sex-determining chromosome: all female gametes contain X chromosomes, and if the fertilized ovum has also received an X chromosome from its father it will be female.

**XYY syndrome.** Chromosomal anomaly in males (presence of an extra Y chromosome) possibly related to impulsive behavior.

**Y chromosome.** Sex-determining chromosome found in half of the total number of male gametes; uniting with X chromosome provided by a female produces a male offspring.

**Zygote.** Fertilized egg cell formed by the union of male and female gametes.

# SUBJECT INDEX

Note: Page numbers in **boldface** type indicate definitions of key terms.

AA (Alcoholics Anonymous), 372–73, 374
AABT (Association for the Advancement of Behavior Therapy), 694
AAMR (*see* American Association on Mental Retardation (AAMR))
Abnormal behavior, **10**; in adolescents (*see* Childhood and adolescent disorders); in ancient times, 32–39; behavioral perspective on (*see* Behavioral perspective); biological perspective on (*see* Biological perspective); causes of, 63–67, 113–15; in children (*see* Childhood and adolescent disorders); classification of, 11–17, 33; defining, 6–11; development of humanitarian approaches to, 39–49; epidemiology of, 17–18; foundations of twentieth-century views of, 49–50; as illness, 40; as maladaptive behavior, 10–11; myths and misconceptions concerning, 7; perspectives for understanding, 67–115 (*see also specific perspectives, i.e.* Biological perspective); popular views of, 5–6, 7; psychodynamic perspective on (*see* Psychodynamic perspective); psychohistory and, 58, 60; research in, 18–25; scientific research and, 50–58 (*see also* Research); treatment approaches for (*see* Treatment approaches; *specific approaches)*
Abnormal psychology, **10**
Abstinence-oriented treatment, for alcohol abuse, 374
Abstinence theory, sexual behavior and, 401
Abstinence violation effect, 374
Accommodation, **96**
ACh (acetylcholine), in Alzheimer's disease, 499, 501
Acquired immunodeficiency syndrome (AIDS): containing epidemic of, 309–10; neuropsychological disorders in, 493–95; psychosocial factors and, 285; sexual dysfunctions and, 437
Acrophobia, 161
Acting out, as defense mechanism, 80
Actuarial procedures, **589**
Acute disorders, **14,** 16
Acute stress, **134**–35
ADC (AIDS dementia complex), **494**
Addictive behavior, 354–97, **355** (*see also* Alcohol abuse and dependence; Drug abuse and dependence); causes of, 385; hyperobesity and, 389–92; pathological gambling and, 392–96
*Addington* v. *Texas,* 682
ADHD (*see* Attention-deficit hyperactivity disorder (ADHD))
Adjustment disorder, **131**–34; with depressed mood, **205**; stress from bereavement and, 133–34; stress from divorce or separation and, 134; stress from unemployment and, 131–33
Adolescence: depression during, 201–2; disorders during (*see* Childhood and adolescent disorders); drug and alcohol abuse during, prevention of, 671–74; gangs during, 542; planning programs for, 555–63; running away during, 539; suicide during, 241, 242, 548; treatment during, 556–58
Adoption studies, 73; of bipolar disorders, 231; in schizophrenia, 462–64; of unipolar mood disorders, 214
Affect (*see also* Depression; Mood disorders); brain damage and, 487; inappropriate, in schizophrenia, 451; positive, 229
Africa, schizophrenia in, 473
African Americans: alcohol abuse among, 357; depression among, 236; hypertension among, 298; IQ testing of, 523; overanxious anxiety disorder among, 544; schizophrenia among, 473; unemployment among, 132
Africans, depression among, 235
Aftercare programs, 680–81
Aggression (*see also* Delinquency); in antisocial personality disorder (*see* Antisocial personality disorder); in conduct disorders, 535, 537; in delusional disorder, 479; exhibitionism and, 410–11; posttraumatic stress disorder and, 137–38; rape and, 425–26; in schizophrenia, 456–57
Agoraphobia, 160, 169–76; treatment for, 191, 193
AIDS (*see* Acquired immunodeficiency syndrome (AIDS))
AIDS dementia complex (ADC), **494**
AIDS-related complex (ARC), **494**
Airplane crashes, 135, 136–37, 151, 154; secondary prevention for survivors of, 676–78
Al-Anon, 372
Alarm reaction, 128, 129, 130, 283
Ala-Teen, 372
*Albertson's Inc.* v. *Workers' Compensation Appeals Board of the State of California,* 154
Alcohol abuse and dependence, 356–74; in antisocial personality disorder, 338; causes of, 363–69; clinical picture of, 357–63; development of, 360; fetal alcohol syndrome and, 75, 361; genetics of, 396; misconceptions about, 358; of parents, 101; prevention of, 671–74; treatment for, 369–74, 640; use of term, 356; warning signs of, 360
Alcohol-abuse counselors, 628
Alcohol amnestic disorder, 363
Alcoholics, **356;** use of term, 356, 372
Alcoholics Anonymous (AA), 372–73, 374
Alcoholism, **356** (*see also* Alcohol abuse and dependence)

Alcohol withdrawal delirium, 362–63
Alexithymia, **274**
Algophobia, 161
Alienists, **47**
ALI (American Law Institute) standard, 688, 689
All-or-none thinking, 194
All-or-nothing reasoning, 223
Alprazolam (Xanax), 614, 615, 638; for anxiety disorders, 181, 190–91
Alter personalities, **267**
Alzheimer's disease (*see* Dementia of the Alzheimer's type (DAT))
AMA (American Medical Association), 694; on masturbation, 402
Amenorrhea, eating disorders and, 296
American Association on Mental Retardation (AAMR): adaptive skills assessment of, 516; mental retardation defined by, 507–8
American Law Institute (ALI) standard, 688, 689
American Medical Association (AMA), 694; on masturbation, 402
American Psychiatric Association (APA), 694; on electroconvulsive therapy, 605; on homosexuality, 404; mental retardation defined by, 507–8
American Psychological Association (APA), 694
American Psychological Society (APS), 694
Amicus curiae, 694
Aminoketones, 613, 614
Amitriptyline (Elavil), 613; for posttraumatic stress disorder, 152
Amnesia: alcohol amnestic disorder and, 363; anterograde, 502; dissociative, 264–66; retrograde, 502
Amnestic syndrome, **492**
Amniocentesis, 510
Amok, 108
Amoxapine (Asendin), 613
Amphetamines: abuse and dependence on, 383–84; for attention-deficit hyperactivity disorder, 532–33
Anaclitic depression, 201, 545
Anafranil (clomipramine): for obsessive-compulsive disorder, 189, 191, 614
Analgesia, in conversion disorder, 260
Analogue studies, **23**
Anal stage, 81
Androgyny, 111
Anesthesia, in conversion disorder, 260
Angina pectoris, 290
Animal magnetism, 53–54
Anorexia nervosa, 108, **292–93**, 294, 296; treatment for, 308
Anorexigenic drugs, for hyperobesity, 391
Antabuse (disulfiram), 370
Anterograde amnesia, 502
Antianxiety drugs, 614–16, 620; abuse and dependence on, 376–77; for antisocial personality disorder, 347; for anxiety disorders, 181, 190–91; side effects of, 614–15; for somatoform disorders, 274
Anticipatory anxiety, 173
Anticipatory phase, in coping with rape, 139
Antidepressant drugs, 612–14, 619–20; for anxiety disorders, 189, 191; MAOIs, 613; SSRIs, 613; for childhood depression, 547; for enuresis, 549; for mood disorders, 236–37; MAOIs, 613; SSRIs, 613; side effects of, 547; for somatoform disorders, 274; tricyclic, 612–13; for unipolar mood disorders, 214, 215
Antigens, **284**
Antimanic drugs, 233, 617, 620 (*see also* Lithium)
Antipsychotic drugs, **609**–12, 619; for schizophrenia, 448
Antisocial personality disorder, 317, **322–23**, 329, 335–49; causes of, 341–46; clinical picture in, 337–41; delinquency and, 540; drug abuse and dependence and, 379; posttraumatic stress disorder and, 144; treatment for, 346–49
Anxiety, 156–97, **157** (*see also* Anxiety disorders); anticipatory, 173; behavioral techniques used with, 86; castration, 81; comorbidity of, 229; defense mechanisms and, 79–81; fear compared with, 158–59; free-floating, 176; moral, 79; neurotic, 79; reality, 79; sexual dysfunctions and, 435–36; uncontrollable and unpredictable frightening events as cause of, 97–98
Anxiety disorders, **159–95**; during childhood and adolescence, 543–45; generalized, 176–82; obsessive-compulsive, 182–90; obsessive-compulsive disorder with, 184; overanxious, 544; panic disorder and agoraphobia, 168–76; phobias, 160–76; separation anxiety disorder, 543–44; treatment for, 190–95, 637–38 (*see also* Antianxiety drugs); unresolved issues concerning, 195–96
Anxiety sensitivity, 175–76
Anxiolytics (*see* Antianxiety drugs)
Anxious apprehension, 158, 176
Anxious hyperarousal, 229
APA (*see* American Psychiatric Association (APA); American Psychological Association (APA))
Apathy, brain damage and, 487
Aphonia, 260
Apolipoprotein-E (ApoE), in Alzheimer's disease, 500, 501
Apprehension, anxious, 158, 176
Approach-approach conflicts, 120
APS (American Psychological Society), 694
Arapesh, 110
Arbitrary inference, 224
ARC (AIDS-related complex), **494**
Asendin (amoxapine), 613
Asians (*see also* China); alcohol abuse among, 365–66; gambling among, 395
Asphyxia, autoerotic, 412, 413–14
Assertiveness therapy, **642–43**
Assessment (*see* Clinical assessment)
Assessment interviews, 574–75, 576, 577
Assimilation, **96**
Association for the Advancement of Behavior Therapy (AABT), 694
Astasia-abasia, 260
Asthma, 296–97
Astraphobia, 161
Asylums, **41–42** (*see also* Hospitalization; Institutionalization; Mental hospitals; Sanatoriums)
Attention-deficit hyperactivity disorder (ADHD), 530, **531–33**; causes of, 531–32; clinical picture in, 531; nutritional deficiencies causing, 77; treatment for, 384, 532–33, 617–18
Attitudes, physical health and, 281–82
Attribution(s), **88–89**, **226**
Attributional style, 88–89; unipolar mood disorders and, 221
Attribution theory, 88–89
Aura, migraines and, 298–99
Australian aborigines, physical illness among, 304
Authoritarian parenting style, 102
Authoritative parenting style, 102
Authority, rejection of, in antisocial personality disorder, 338
Autism, 451, **551–55**; causes of, 554; clinical picture in, 552–54; treatment for, 554–55, 640
Autistic-savants, 553
Autoerotic asphyxia, 412, 413–14

Autogynephilia, 416
Autonomic excess, physical health and, 282–83
Autonomic reactivity, psychogenic physical illness and, 301
Autonomy, unipolar mood disorders and, 220
Autosomes, 71
Aventyl (nortriptyline), 613
Aversion therapy, **639–40**; for sex offenders, 429
Aversive conditioning, for alcohol abuse, 371
Aversive emotional arousal, in antisocial personality disorder, 341–43
Aversive stimuli, **86**
Avoidance response, conditioned, 84
Avoidant personality disorder, 317, **324**–26, 329; treatment for, 335
Axes, of DSM, 13–14, 315
AZT (zidovudine), for AIDS, 494

Bad-me, 93–94
Barbiturates, abuse and dependence on, 384–85
B & D (bondage and discipline), 411
Bedlam, 41
Bedwetting, 548–49
Behavioral activation system, in antisocial personality disorder, 342
Behavioral contracting, **642**
Behavioral inhibition system, in antisocial personality disorder, 342
Behaviorally inhibited children, 75; phobias and, 165
Behaviorally uninhibited children, 75–76
Behavioral medicine, 279–80 (*see also* Physical health and illness)
Behavioral perspective, **56**–58, 83–85; generalization and discrimination and, 83–85; on generalized anxiety disorder, 179; impact of, 85, 86; learning and, 83–85; on obsessive-compulsive disorder, 186; on panic disorder, 173–74; roots of, 57–58; on social phobia, 167–68; on specific phobia, 163–64; on unipolar mood disorders, 222–23
Behaviorism, **57**
Behavior-modification techniques, 86, 641–42; for psychogenic physical illness, 306–7
Behavior therapy, 85, 86, 89, **636–44**; for alcohol abuse, 371–72; for Alzheimer's disease, 501; for antisocial personality disorder, 347–48; for anxiety disorders, 192–93; assertiveness therapy, 642–43; for attention-deficit hyperactivity disorder, 533; for autism, 555; aversion therapy, 371, 429, 639–40; behavior-modification techniques of, 86, 306–7; biofeedback treatment, 299, 306, 643–44; for borderline personality disorder, 334–35; for childhood and adolescent anxiety disorders, 545; for conduct disorders, 537–38; for delinquency, 542; evaluation of, 644; extinction in, 636–38; for hyperobesity, 391–92; modeling and, 640–41; systematic desensitization, 89, 192, 638–39; systematic use of reinforcement in, 641–42
*The Bell Curve* (Herrnstein and Murray), 523
La belle indifférence, **262**
Benzedrine, abuse and dependence on, 383
Benzodiazepines, 614, 615–16, 621; for anxiety disorders, 181, 190–91; withdrawal of, 191
Bereavement (*see also* Grief); stress from, 133–34
Beta-blockers, for social phobias, 191
La Bicetre, 41–42; Pinel's experiment at, 42–44
Bilirubin encephalopathy, 511
Biochemical causal factors: for bipolar disorders, 232–33; for schizophrenia, 465–66; for unipolar mood disorders, 214–15
Biochemical imbalances, 69, 70
Biofeedback, **299, 643–44**; for headaches, 299; for psychogenic physical illness, 306
Biological causal factors, 68–78; for alcohol abuse, 363–66; for antisocial personality disorder, 341–44; for attention-deficit hyperactivity disorder, 532; for bipolar disorders, 231–33; brain dysfunction as, 76; for childhood depression, 545, 547; for combat stress, 143–44; constitutional liabilities as, 73–76; for drug abuse and dependence, 364–65, 379; for generalized anxiety disorder, 181–82; genetic defects as, 69, 71–73; for hyperobesity, 389–90; neurotransmitter and hormonal imbalances as, 69, 70; for panic disorder, 172–73; for personality disorders, 330; for phobias, 165–66, 167–68; physical deprivation or disruption as, 76–78; primary prevention and, 669–70; for psychogenic physical illness, 300–301; for schizophrenia, 460–69; for somatfororm and dissociative, 270; for specific learning disorders, 521; for unipolar mood disorders, 213–17
Biological challenge procedures, 172
Biological decompensation, under executive stress, 128–29
Biological perspective, 68–78; classification and, 51–52; early advances achieved as result of, 52; establishment of brain pathology as causal factor and, 50–51; impact of, 78; roots of, 50, 51
Biological rhythm disturbances: bipolar disorders and, 233; in unipolar mood disorders, 216–17
Biological therapy, 78, 600–622; for alcohol abuse, 369–70; coma, 602–6; early, 601–8; pharmacologic (*see* Pharmacologic therapy); for psychogenic physical illness, 305–6; psychosurgery, 606–8
Biopsychosocial perspective, 114–15; on anxiety disorder, 196; on pharmacologic therapy, 618–21; on psychopathy, 345–46
Bipolar disorders, 200, 201, **201,** 209–12, 231–36; causes of, 231–35; cyclothymia, 209–10; schizoaffective, 212; with seasonal pattern, **211–12**; treatment for, 232–33, 233, 616–17
Biting manias, 262
Black Americans (*see* African Americans)
Black Death, 37
Blackouts, alcohol abuse and, 360
Bleeding, as therapy, 602
Blindness, hysterical, 260
Blood-alcohol discrimination training, for alcohol abuse, 371
Blood alcohol levels, 359
Blood-injury phobia, **161,** 162
Blood pressure elevation, 297–98; treatment for, 307
Bodily magnetism, 40
Bondage and discipline (B & D), 411
Borderline personality disorder, 82, 317, **323–24**; causes of, 331; childhood sexual abuse and, 439; comorbidity of, 324; treatment for, 334–35
Boxers, petechial hemorrhages and, 503–4
Boys (*see* Gender differences; Men and boys)

BPRS (Brief Psychiatric Rating Scale), 577–78

Brain: alcohol and, 360; in Alzheimer's disease, 499–500; in bipolar mood disorders, 233; cocaine and, 382; in mental retardation, 509–10, 513–14; in obsessive-compulsive disorder, 188–89; panic disorder and, 173; physical illness and, 286; psychoactive substance abuse and, 364, 365; in schizophrenia, 462, 465–66, 467–69; in somatoform and dissociative, 270; in unipolar mood disorder, 215–17

Brain damage (*see also* Head injury; Neuropsychological disorders); delinquency and, 540; diffuse, 486; from electroconvulsive therapy, 605; focal, 486–87; location of, 488–90

Brain pathology, 76 (*see also* Neuropsychological disorders); establishment as causal factor, 50–51; neurological examination and, 571–72; nutritional deficiencies causing, 77; in unipolar mood disorders, 215–16

*Breakdown* (Sutherland), 5

Brecksville treatment program, for gambling, 395

Brief Psychiatric Rating Scale (BPRS), 577–78

*The Broken Heart* (Lynch), 303

Broken homes (*see* Divorce)

Buffalo Creek flood, 137, 528

Bulimia nervosa, **294–96**; treatment for, 307, 308, 614

Bupenorphine, for drug withdrawal, 381

Bupropion, 613

Caffeine: abuse and dependence on, 388; panic attacks and, 172

Caffeinism, 388

Camphor, convulsions induced by, 602

Canadian Psychiatric Association, on electroconvulsive therapy, 605

*The Canon of Medicine* (Avicenna), 35–36

CAPER framework, 630–31

Capsulotomy, 607

Carbamazepine (Tegretol): for antisocial personality disorder, 347; for bipolar disorder, 233, 617

Carbon dioxide, panic attacks and, 172

Cardiopulmonary resuscitation (CPR), 290

Case studies, **24**

Castration, of sex offenders, 429–30

Castration anxiety, **81**

Catastrophic events (*see* Disasters)

Catastrophizing, panic disorder and, 174–76

Catatonic schizophrenia, 453, **454–56**

Categorical approach, **27**, 530; and personality disorders, 315, 351

Catharsis, **55**

CAT (computerized axial tomography) scan, **571**

Causation, **21–22**; 63–65

CBC (Child Behavior Checklist), 530

CBT (*see* Cognitive-behavioral therapy (CBT))

C & E (consultation and education), 676

Cerebral edema, 503

Cerebral hemispheres, functions of, 489–90

Character (*see* Personality disorders; Personality)

CHD (*see* Coronary heart disease (CHD))

Chemical castration, of sex offenders, 429–30

Chernobyl nuclear accident, 123, 124

Chicago Juvenile Psychopathic Institute, 56

Child abuse, 99, 558–61; causes of, 560; dissociative disorders and, 270–71, 272–73; personality disorders and, 330–31; prevention of, 560–61; sexual, 417–23, 439–40, 559–60

Child advocacy programs, 561–62

Child Behavior Checklist (CBC), 530

Childhood: abuse during (*see* Child abuse); advocacy programs and, 561–62; assessment interviews during, 575; communication with parents during, 103; court testimony of children and, 418, 419–21; family therapy during, 546; maladaptive peer relationships during, 104–6; nutritional deficiencies during, 77; parental deprivation during, 98–99, 100; parenting styles and, 101–3; pathogenic families during (*see* Pathogenic families); pharmacologic therapy during, 617–18; planning programs for, 555–63; play therapy during, 546; running away during, 539; suicide during, 241–42, 548; trauma during, 99–100, 271, 272–73; treatment during, 556–58; vulnerability during, 528, 529

Childhood and adolescent disorders, 531–51; anxiety disorders, 543–45, 546; attention-deficit hyperactivity disorder, 531–33; autism, 551–55; classification of, 528–30; clinical pictures in, 528; conduct, 345–46, 533–38; delinquency (*see* Delinquency); depression, 201, 545, 547–48; disasters and, 528, 529; drug and alcohol abuse, prevention of, 671–74; functional encopresis, 549; functional enuresis, 548–49; gender identity disorders, 414–15; mental retardation (*see* Mental retardation); sleepwalking, 549–51; tics, 551; treatment for, 555–63

Children's Defense Fund, 562

China: coping strategies in, 109; demonology in, 32; gambling in, 392; marijuana use in, 386

Chinese, early views of mental disorders in, 36

Chlordiazepoxide (Librium), 614; for alcohol withdrawal, 362–63; for anxiety, 181

Chlorpromazine (Thorazine), 609–10

Chorionic villus sampling, 510

Chromosomal anomalies, 71; in mental retardation, 509

Chronic disorders, **16**

Cingulotomy, 606–7

Circadian rhythm disturbances (*see* Biological rhythm disturbances)

Classical conditioning, **57**, **84**; biofeedback and, 643; of immunosuppression, 286; of phobias, 163–64, 167

Classic migraine, 298–99

Classification, **11**; of abnormal behavior, 11–17; unresolved issues concerning, 26–27

Claustrophobia, 161

Clergy: pedophilia and, 423; providing psychotherapy, 627, 628

Client: clinician's rapport with, 570; therapeutic harm to, 663–64; use of term, 17

Client abuse, 663–64

Client-centered therapy, 650–56

Clinical assessment, 566–98; of dangerousness, 683–87; information sought in, 568–69; integration of data and, 594–96; of mental retardation, 516; physical, 570–74; psychosocial (*see* Psychosocial assessment); rapport between clinician and client and, 570; types of assessment data and, 569–70

Clinical picture, **11**

Clinical Problem Checklist, 575

Clinical psychologists, **627,** 628
Clinical psychology, **10**
Clinicians *(see* Mental health professionals; Therapists; *specific professions)*
Clomipramine (Anafranil), for obsessive-compulsive disorder, 189, 191, 614
Clonidine, for autism, 554
Clorazepate (Tranxene), 614
*The Clouds* (Aristophanes), 31
Clozapine, 612; for schizophrenia, 466
Cluster headaches, 299
Cocaine, **381;** abuse and dependence on, 381–83
Cocaine bug, 381
Coconut Grove fire, 135
Codeine, 377
Cognex (tacrine), for Alzheimer's disease, 499, 501
Cognitive-behavioral perspective, **87–89;** on childhood depression, 547; on hyperobesity, 390; impact of, 89; on unipolar mood disorders, 222–25
Cognitive-behavioral therapy (CBT), 644–50, **645,** 661; for alcohol abuse, 371, 374; for anxiety disorders, 192–93, 194; of Beck, 647–49; for borderline personality disorder, 334–35; evaluation of, 649–50; for mood disorders, 238–39; for psychogenic physical illness, 306, 307–8; rational-emotive, 645–46; stress-inoculation, 646–47
Cognitive causal factors: for generalized anxiety disorder, 179–81; for obsessive-compulsive disorder, 186, 188; for panic disorder, 173–76; for unipolar mood disorders, 220–21, 223–26
Cognitive deficits (*see also* Mental retardation); in antisocial personality disorder, 344; in autism, 553
Cognitive perspective (*see* Cognitive-behavioral perspective)
Cognitive processes, 87
Cognitive restructuring, **86;** for sex offenders, 429
Cognitive therapy: for antisocial personality disorder, 348–49; for anxiety disorders, 193; for depression, 238–39; for personality disorders, 333–34
Cognitive variables, anxiety disorders, 165, 168, 173–76, 180–81, 186, 188
Cohesive family model, for treatment of conduct disorders, 537
*Colloquia Mensalia* (Luther), 39
Coma therapy, 603
Combat: conversion disorder and, 259, 260; stress caused by (*see* Combat stress); suicide and, 244; vulnerability to disorders following, 112
Combat fatigue, 141
Combat stress, 140–45; causes of, 143–45; clinical picture in, 142–43; long-term effects of, 145
*Coming of Age in Samoa* (Mead), 107
Commitment, 681–83
Common migraine, 299
Communication: disturbances of, in schizophrenia, 449–50; faulty, schizophrenia and, 471–72; interpersonal accommodation and, 94; parent-child, 103; of suicidal intent, 246
Community, right to live in, 682
Community mental health workers, 628
Comorbidity, 13, 27; of depression and anxiety, 229; of borderline personality and depression, 324; of obsessive-compulsive disorder, 183–84; of personality disorders, 324, 330, 349
Compazine (prochlorperazine), 610
Compensation (*see* Financial compensation)
Comprehension, brain damage and, 487
Compulsions, **182** (*see also* Obsessive-compulsive disorder (OCD); Obsessive-compulsive personality disorder)
Compulsive gambling (*see* Pathological gambling)
Computer(s): in clinical diagnosis, 576–77, 596–97; personality test interpretation by, 589
Computerized axial tomography (CAT scan), **571**
Computerized Diagnostic Interview for Children, 575
Concentration camps: apathy deaths in, 282; post-traumatic stress disorder among survivors of, 145, 146–47
Concordance rates, 72
Concussions, 504
Conditioned avoidance response, 84
Conditioned response (CR), 84
Conditioned stimulus (CS), 84
Conditioning (*see also* Classical conditioning; Operant conditioning); aversive (*see* Aversion therapy); for enuresis, 549; hyperobesity and, 390; interoceptive, 173–74, 193; for sleepwalking, 550; systematic desensitization and, 89, 192, 638–39
Condoms, 437
Conduct disorders, 345–46, 533–38, **534**
Conflicts: in psychoanalytic perspective, 81–82; as stressors, 120–21
Conscience, 79; in antisocial personality disorder, 338, 341–43
Consensus Development Conference on ECT, 605
Consensus model, for treatment of dissociative identity disorder, 274–75
Constitutional liabilities, 73–76; physical handicaps as, 73–75; primary reaction tendencies and temperament as, 75–76
Consultation and education (C & E), 676
Content interpretation, of MMPI, 584
Context, defining abnormal behavior and, 9
Contingency management, 641
Contractures, hysterical, 260
*Contrariis contrarius* principle, 35
Control: lack of, anxiety and, 97–98, 179–80; parental, 102–3; uncontrollable and unpredictable frightening events as cause of anxiety and, 97–98
Control group, **21**
Controlled-drinking treatment, 372
Controlled Substance Act of 1970, 384
Contusions, of brain, 504
Conversion disorder, 253, **258–63,** 275
Convulsive therapy, 602–6; electroconvulsive (*see* Electroconvulsive therapy (ECT))
Coping strategies, **120,** 126–31; physical health and, 282; for rape, 139–40
Coprolalia, 551
Coronary heart disease (CHD), **288;** causes of, 300–301; type A behavior pattern and, 288–92, 302
Correlation, **21–22**
Corticovisceral control mechanisms, 301
Cortisol: alarm reaction and, 130; in unipolar mood disorders, 215
Counseling (*see also* Psychotherapy); couples, 654–56; for delinquency, 542; of rape victims, 140; by telephone hot lines, 674, 676, 678
Counseling psychologists, 628

Counselors (*see* Mental health professionals; Therapists; *specific professions*)
Counter-transference, **634**
Couples counseling, **654**–56
*The Courage to Heal* (Bass and Davis), 419
Court cases: on appropriate treatment, 618; court testimony of children and, 418, 419–21; on electroconvulsive therapy, 604–5; insanity defense and, 153, 590, 687–89, 699; on patient rights, 682; posttraumatic stress disorder as defense in, 154; psychological assessment in, 589–90; rape and, 426–27
Coverants, 644–45
CPR (cardiopulmonary resuscitation), 290
CR (conditioned response), 84
Crack cocaine, 381, 382–83
Cranial anomalies, mental retardation associated with, 513–14
Criminal behavior (*see also* Delinquency); in antisocial personality disorder, 341
Crisis, **124**–25
Crisis in Child Mental Health: Challenge for the 1970s, 561
Crisis intervention, **125**, 152–53, 674–76; short-term, 674, 675; for suicide, 247–48; telephone hot lines and, 674, 676, 678
Criterion group, **21**
Cross-dressing, 407–9
Cross-gender identification, **414**
CS (conditioned stimulus), 84
Cultural causal factors (*see* Sociocultural causal factors; *specific factors, i.e.* Socioeconomic status)
Cultural-familial retardation, **514**–16; unresolved issues concerning, 522–23
Cultural supports, 123–24
Culture, defining abnormal behavior and, 8
Custodial confinement, freedom from, 682
Cyclothymia, **209**–10

Dallas plane crash, 154
Dalmane (flurazepam), 614
Dancing manias, 37, 40
Dangerousness: assessment of, 683–87; commitment and, 682–83
DAT (*see* Dementia of the Alzheimer's type (DAT))
DDAVP (desmopressin), for enuresis, 549
Deafness, hysterical, 260
Death (*see also* Suicide); alcohol abuse and, 356–57, 362–63; cardiac, sudden, 290; cocaine-related, 382; depression and, 240; stress from, 133–34
Death instincts, 79
Debriefing sessions, following disasters, 678
Decatastrophizing, 194
*The Deception of Demons* (Weyer), 40
Decompensation: under executive stress, 128–31; schizophrenia and, 472
Defense mechanisms (*see* Ego-defense mechanisms)
Defense-oriented response, **127**–28
Defense-oriented strategies, in bipolar disorders, 234–35
Degeneracy theory, sexual behavior and, 401
Deinstitutionalization, 18, 689–93, **690**
Delinquency, 534, 538–43; causes of, 538–42; dealing with, 542–43; incidence and severity of acts and, 538, 539; socioeconomic status and, 104
Delirium, **491**
Delirium tremens, 362–63
Delusional disorder, **475**–82; causes of, 479–81; clinical picture in, 477–79; treatment for, 481
Delusional disorders, 443
Delusional neuropsychological syndromes, 492–93
Delusions, **450**; in borderline personality disorder, 324; in delusional disorder, 477–78, 479; in major depressive disorder, 206–7; paranoid, 477–78; in schizophrenia, 457
Démence précoce, 444 (*see also* Schizophrenia)
Dementia, 488, 490, **491**–92; presenile, 495, 496; senile, 495 (*see also* Dementia of the Alzheimer's type (DAT)); vascular, 502
Dementia of the Alzheimer's type (DAT), **495**–502; causes of, 499–500; clinical picture in, 496–99; Down syndrome and, 500, 512; treatment for, 500–502
Dementia praecox, **444** (*see also* Schizophrenia)
Demonology, 32–33, 274; during Middle Ages, 36, 37–39, 60; refutations of, 40, 41
Denial of reality, 80
Dental phobias, 162
Deoxyribonucleic acid (DNA), 71
Dependent personality disorder, 317, **326**, 329; treatment for, 335
Depersonalization disorder, **269**
Depo-Provera (medroxyprogesterone acetate), for sex offenders, 430
Depression, **201** (*see also* Bipolar disorders); anaclitic, 201, 545; behavior-modification techniques used with, 86; in bipolar disorder, 210; causes of, during childhood, 545, 547–48; cognitive antecedents of, 97, 223–26; comorbidity of with borderline personality with anxiety disorders, 239, 324; endogenous, 219; following grief, 133; immune function and, 285; learned helplessness as cause of, 23, 225–26; major, 206–9; mild to moderate, 201, 204–5; normal, 202–3; obsessive-compulsive disorder with, 183–84; in parents, 101; physical illness and, 76; postpartum, 203, 204; treatment for, 605, 648, 649, 661 (*see also* Antidepressant drugs); Victorian treatment of, 47
Depressive personality disorder, 317, **328**
Depressive syndrome, 8
Depressogenic schemas, 223
Deprivation: parental, 98–99, 100; physical, 76–78
Derealization, **269**
Descriptive diagnosis, MMPI and, 584
Desensitization, **86**; systematic (*see* Systematic desensitization)
Desipramine, for childhood depression, 547
Desire phase, **430**
Desmopressin (DDAVP), for enuresis, 549
Desyrel (trazodone), 613
Detoxification, for alcohol abuse, 369–70
Detroit plane crash, 678
Developmental obesity, 390
Developmental perspective, on antisocial personality disorder, 345–46
Developmental psychopathology, **527** (*see also* Childhood and adolescent disorders)
Dexamethasone suppression test (DST): in bipolar mood disorders, 233; in unipolar mood disorders, 215
Dextroamphetamine (Dexedrine), abuse and dependence on, 383
*Diagnostic and Statistical Manual (DSM):* anxiety disorders and, 157, 158, 159; axes of, 13–14, 27; classification of mental disorders in, 12–16; cyclothymia and, 209;

DSM-IV, 8–9; homosexuality and, 404; mental disorder defined by, 8–9; personality disorders and, 314–15, 335, 336, 349–51; psychogenic illnesses and, 280; schizophrenia and, **450, 451,** 476; somatoform and dissociative disorders and, 275–76; stress and, 135; stressors and, 131
Diagnostic standard, MMPI as, 584
Dialectical behavior therapy, for borderline personality disorder, 334–35
Diathesis-stress models, 65–67, **219–20**, 220–22
Diazepam (Valium), 614
Dibenzodiazepines, 612
Dichotomous reasoning, 223
DID (*see* Dissociative identity disorder (DID))
Diet (*see also* Malnutrition); in attention-deficit hyperactivity disorder, 532
Dieting: anorexia nervosa and, 292–93, 294, 296; for hyperobesity, 391, 392
Differential reinforcement, 85
Differential reinforcement of other responses (DOR), 640
Dimensional approach, **27,** 530
Disasters (*see also* Plane crashes); during childhood, 528, 529; reactions to, 135–38
Disaster syndrome, **135**–38
Disaster workers, treatment for, 150, 151
Discipline: delinquency and, 540–41; severe, 102; style of, 101–3
*Discovery of Witchcraft* (Scot), 41
Discrimination, **85;** racial, 112–13
Disorganized schizophrenia, 453, **456**–57
Displacement, as defense mechanism, 80
Dissociation, **263**
Dissociative amnesia, 264–66, **265**
Dissociative disorders, **253–54**, 263–76; amnesia and fugue, 264–66; causes of, 269–74; childhood sexual abuse and, 439; continuum of, 264; depersonalization, 269; of identity (*see* Dissociative identity disorder (DID)); treatment for, 274–75; unresolved issues concerning, 275–76
Dissociative Experiences Scale, 271
Dissociative identity disorder (DID), 264, 266–68; causes of, 270–71, 272, 274; legal issues related to, 699; treatment for, 274–75
Distress, **120**
Disulfiram (Antabuse), 370
Divorce, 103–4; conduct disorders and, 537; effects on children, 104; stress and, 123, 134
*Dixon* v. *Weinberger*, 682
DNA (deoxyribonucleic acid), 71
*Donaldson* v. *O'Connor*, 682
Dopamine hypothesis, **465,** 465–66
DOR (differential reinforcement of other responses), 640
Double-approach conflicts, **121**
Double-avoidance conflicts, 121
Double-bind communication, **471**
Down syndrome, 71, 509, **510**–13; Alzheimer's disease and, 500, 512
Dream analysis, **55,** 83, 633
Dream induction, 633
Drug abuse and dependence, 375–89; in antisocial personality disorder, 338; caffeine and nicotine and, 388–89; delinquency and, 540; hallucinogens and, 385–86; marijuana and, 386–88; narcotics and, 375–81; prevention of, 671–74; sedatives and, 384–85; stimulants and, 381–84
Drug-abuse counselors, 628
Drug therapy (*see* Pharmacologic therapy)
DSM-IV, **12** *(see also Diagnostic and Statistical Manual (DSM))*
DST (dexamethasone suppression test): in bipolar mood disorders, 233; in unipolar mood disorders, 215
D-Tree, 576–77
Durham Rule, 688, 689
Duty to protect, 686–87
Dynamic formulation, **569**
Dynamic psychotherapy, time-limited, 635
Dysfunctional beliefs, **220–21**, 223
Dyslexia, 520
Dyspareunia, **434**
Dysrhythmia, **571**
Dysthymia, **204**

EAPs (employee assistance programs), 695
Eating disorders, 108, 292–97 (*see also* Hyperobesity); causes of, 303, 305; treatment for, 307, 308, 614
Ebers papyrus, 32
ECA (*see* Epidemiologic Catchment Area (ECA) study)
Echolalia, **552;** in catatonic schizophrenia, 455
Echopraxia, in catatonic schizophrenia, 455
Eclectic approach, 114
Economic problems, vulnerability to disorders and, 113
ECT (electroconvulsive therapy), 603–6; for mood disorders, 237; for unipolar mood disorders, 214
*The Eden Express* (Vonnegut), 5
Education: of autistic children, 554–55; for drug and alcohol abuse prevention, 671–72; of mentally retarded individuals, 517–18
Education for All Handicapped Children Act of 1975 (Public Law 94-142), 517
Edwin Smith papyrus, 32
EE (expressed emotion), 239, 472
EEG (electroencephalogram), 571
*Egeland* v. *City of Minneapolis,* 154
Ego, **79**
Ego-defense mechanisms, 79–81, 83, 127–28; in anxiety disorders, 163, 179, 185–86
Egypt: demonology in, 32; incest in, 423; treatment approaches in, 34
Egyptian papyri, 32
Ejaculatory disorders, 400
Elavil (amitriptyline), 613; for posttraumatic stress disorder, 152
Electra complex, **81**
Electrical stimulation, as therapy, 602
Electroconvulsive therapy (ECT), **603**–606; for mood disorders, 237; for unipolar mood disorders, 214
Electroencephalogram (EEG), **571**
*Elements of Physiology* (von Haler), 50
Emetine hydrochloride, for alcohol abuse, 371
Emotional control, brain damage and, 487
Emotional insulation, 80
Empirical keying, 583
Employee assistance programs (EAPs), 695
Encephalopathy, bilirubin, 511
Encopresis, **549**
Endogenous depression, 219
Endorphins, 379; alarm reaction and, 130; physical illness and, 286
Enuresis, **548–49**
Environmental factors: in attention-deficit hyperactivity disorder, 532; in conduct disorders, 536–37; generalized anxiety disorder and, 179–80; genotype and, 72; need for stimulation and, 77–78; overanxious anxiety disorder and, 544; shared and non-

shared influences and, 73; social, impact on mental disorders, 106–10; sociocultural, 110–11
Environmental intervention, for alcohol abuse, 371
Epidemiologic Catchment Area (ECA) study: anxiety disorders in, 160, 162; mood disorders in, 236; obsessive-compulsive disorder in, 182; schizophrenia, 444
Epidemiology, **17–18**; of coronary heart disease, 291; correlational studies and, 22
Episodic disorders, **16**
Equanil (meprobamate), 614
Erectile disorders, 432, 435; treatment for, 438–39
Erotic target location, 414
Erotomanic delusional disorder, 476
Eskimos, alcohol abuse among, 365–66
Essential hypertension, **297**–98
Estrogens, for treatment of transsexuals, 416
Ethics: brain damage and, 487; in experimental research, 22–23
Ethnic groups (*see also specific groups, i.e.* African Americans); mental retardation and, 523; prejudice and discrimination and, 112–13
Eustress, **120**
Excitement, in catatonic schizophrenia, 455
Excitement phase, **430–31**
Executive branch of the personality, 79
Executive stress, decomposition under, 128–31
Exhaustion: combat, 141; in general adaptation syndrome, 128, 130, 286–87
Exhibitionism, **410**–11
Existential perspective, 90
Existential psychotherapy, **652**–53
Exner Comprehensive Rorschach System, 581
Exorcism, **32–33**, 274; during Middle Ages, 38–39
Experiment(s), N=1, **24**
Experimental method, **22–24**
Exposure therapy: for anxiety disorders, 192–93; for obsessive-compulsive disorders, 187; for posttraumatic stress disorder, 153
Expressed emotion (EE), 239, **472**
Extinction, **84;** in behavior therapy, 636–38; unipolar mood disorders and, 222–23

Factitious disorders, **254;** conversion reactions versus, 262
Factor analysis, **588**
Failure to thrive (FTT) syndrome, 99
False memories, **271**
False Memory Syndrome Foundation, 422
Families (*see also* Genetic factors; Parent(s)); antisocial personality disorder and, 344–45; crisis intervention in, 675; cultural-familial retardation and, 514–16, 522–23; pathogenic (*see* Divorce; Pathogenic families); personality disorders and, 332–33
Family history, 72
Family interventions, for drug and alcohol abuse prevention, 672
Family therapy, 656–59; with children, 546; for psychogenic physical illness, 308; for schizophrenia, 475
Fantasy, as defense mechanism, 80
Fear(s), **158** (*see also* Phobias); anxiety compared with, 158–59; conditioning of, 84; interoceptive, 173–74; offean, 173; prepared, 165, 167; sexual dysfunctions and, 435–36
Fellatio, 402
Female orgasmic disorder, **433–34**
Female pollution, 402
Female sexual arousal disorder, **432**–33
Femininity: Horney's view of, 92–93; role expectations and, 111
Fetal alcohol syndrome, 75, 361
Fetal development (*see* Prenatal development)
Fetishism, **407**–409; transvestic, 407–9, 414
Fight or flight response, 158; physical health and, 283
Financial compensation: conversion disorder and, 263; malingering and, 698–99; for work, right to, 682
Fixated pedophiles, 422
Fixation: as defense mechanism, 80; in obsessive-compulsive disorder, 185; at psychosexual stages, 81
Flashbacks, **386**
Flight into reality, bipolar disorders and, 234
Flooding, **637**, 638
Florida Everglades plane crash, 137
Fluoxetine (Prozac), 613, 621; for bulimia nervosa, 614; for mood disorders, 237; for obsessive-compulsive disorder, 189, 191, 614; for posttraumatic stress disorder, 152
Fluphenazine (Prolixin), 610
Flurazepam (Dalmane), 614
Fluvoxamine, for panic disorder, 614
Folie à deux, 475, 477
Food-additive theory, of attention-deficit hyperactivity disorder, 532
Forced relocation, posttraumatic stress disorder caused by, 148–50
Forensic psychiatry, **681**–93 (*see also* Court cases); assessment of dangerousness and, 683–87; commitment process and, 681–83; deinstitutionalization and, 689–93; insanity defense and, 687–89; law-mental health interface and, 698–700
Forensic psychology, **681**
Formal thought disorder, 449–50
Foster homes, for mentally retarded individuals, 517
Fragile X syndrome, 509, 554
Framingham Heart Study, 291
France, alcohol abuse in, 369
Free association, **55,** 83, **632,** 633
Free-floating anxiety, 176
Frontal lobes, in schizophrenia, 467–68
Frustrations: physical illness and, 302; as stressors, 120
FTT (failure to thrive) syndrome, 99
Fugue, **265**–66
Functional encopresis, 549
Functional enuresis, 548–49
*Fundamentals of Psychoanalysis* (Freud), 79

GABA (gamma aminobutyric acid): benzodiazepines and, 615; generalized anxiety disorder and, 181
GAD (*see* General adaptation syndrome (GAD))
GAD (general adaptation syndrome), 128–30, 283, 286–87
GAD (generalized anxiety disorder), 176–82; causes of, 179–82
GAF (Global Assessment of Functioning) Scale, 14, 15
Gamblers Anonymous, 394, 395
Gambling (*see* Pathological gambling)
Gamma aminobutyric acid (GABA): benzodiazepines and, 615; generalized anxiety disorder and, 181
Gangs, 542
Gay men (*see* Homosexuality)

GBMI (guilty but mentally ill), 689
Geel shrine, 42
Gender differences: in alcohol abuse, 357; in enuresis, 548; in prevalence of mental disorders, 18; in suicide, 241; in unipolar mood disorders, 227
Gender dysphoria, **414**
Gender identity disorders, **414–16**; of childhood, 414–15; transsexualism, 415–16; treatment for, 416
Gender roles, sexual dysfunctions and, 437
Gene expression, 71–72
Gene-mapping studies, of bipolar disorders, 231–32
General adaptation syndrome (GAD), **128–30**, 283, 286–87
Generalization: autistic children's problems with, 555; in conditioning, **85**; of research results, 20–21
Generalized anxiety disorder (GAD), 176–82; causes of, 179–82
Generalized anxiety disorder, treatment for, 192, 614
General paresis (*see* Syphilis)
General physical examination, 571
Genetic defects, 69, 71–73; chromosomal anomalies and, 71; faulty genes and, 71–73; methods for studying, 72–73, 74
Genetic factors: in alcohol abuse, 363–66, 396; in alcohol abuse and dependence, 396; in Alzheimer's disease, 500; in antisocial personality disorder, 341, 345–46; in autism, 554; in bipolar disorders, 231–32; in conduct disorders, 535–36; in delinquency, 539–40; in generalized anxiety disorders, 181; gender differences in unipolar mood disorders and, 227; in hyperobesity, 389–90; in mental retardation, 509; in obsessive-compulsive disorder, 188; panic disorder and, 173; in personality disorders, 330; phobias and, 165; primary prevention and, 669–70; in psychogenic physical illness, 300–301; in schizophrenia, 460–65; in somatoform and dissociative, 270; in unipolar mood disorders, 213–14
Genital stage, 81
Genotype, **71–72**
German measles, mental retardation and, 509, 511
Gestalt processing, 489
Gestalt therapy, **653**
Girls (*see* Gender differences; Women and girls)
Global Assessment of Functioning (GAF) Scale, **14**, 15
Gloucester Asylum, 44
Good-me, 93–94
Grades, stress and, 121
Gratification, delay of, in antisocial personality disorder, 343–44
*Great and Desperate Cures* (Valenstein), 606
Great Depression, suicide during, 245
Greeks: demonological views of, 32–33; philosophical and medical concepts of, 33–34; on suicide, 249
Grief, 202–3; physical illness and, 302–3; regression and, 222; stress from, 133–34
Group homes, for mentally retarded individuals, 517
*The Group of Schizophrenias* (Bleuler), 444
Group therapy, 651; for alcohol abuse, 370–71; for pathological gambling, 395
Guilt: conversion disorder and, 262–63; posttraumatic stress disorder and, 136–37; among rape victims, 139
Guilty but mentally ill (GBMI), 689

Halfway houses, for mentally retarded individuals, 517
Hallucinations, **451**, 457–58; in borderline personality disorder, 324; cocaine-induced, 381; in delusional disorder, 478–79; in major depressive disorder, 206–7; in schizophrenia, 456
Hallucinogens, **385**; abuse and dependence on, 376–77, 385–86
Haloperidol (Haldol), 610, 611–12; for autism, 554
Halstead-Reitan battery, 573; in forensic cases, 589
Hamilton Rating Scale for Depression (HRSD), 578
Hangovers, alcohol abuse and, 360
Harrison Act of 1914, 377–78
Hashish, **386**
Headaches, 298–300; treatment for, 307
Head injury, 502–6; clinical picture in, 502–5; treatment for, 505–6
*Health Psychology*, 280
Health psychology, **280**; primary prevention and, 670
Heart attack, 290
Heart disease (*see* Coronary heart disease (CHD))
Hebephrenic schizophrenia, 456–57
Hebrews, demonological views of, 32
Helplessness, physical health and, 281–82
Helplessness theory of depression, 23, 225–26, 228
Hematoma, subdural, 503
Hemlock Society, 249
Hemorrhage: intracranial, 503; petechial, 503–4
Heroin, **375–77**, 378–79
Hippocampus, in Alzheimer's disease, 499
Hispanic Americans, depression among, 236
History, interpretation of, 58, 60
*History of Psychiatry*, 504
Histrionic personality disorder, 317, **320–21**, 329
HIV infection (*see* Acquired immunodeficiency syndrome (AIDS))
*Holiday of Darkness* (Endler), 5
Homelessness, 691–92
Homeostasis, 76
Homosexuality, 402–4; gender identity disorders and, 414–15; in Melanesia, 402; as nonpathological variation, 404, 405–6; as sickness, 403; transsexualism and, 415–16
Hopelessness of depression, 226–28
Hormones, **69**; gender differences in unipolar mood disorders and, 227; imbalances of, 69; physical illness and, 286; postpartum depression and, 203; for treatment of transsexuals, 416; in unipolar mood disorders, 215
Hospital(s) (*see also* Institutionalization; Mental hospitals); clinical assessment in, 578; psychotherapy in, 627–28
Hospitalization (*see also* Institutionalization; Mental hospitals); aftercare programs and, 680–81; for alcohol abuse, 369, 373; assessment of dangerousness and, 683–87; commitment process and, 681–83; decrease in, 18; for drug withdrawal, 380; for gambling, 395; for schizophrenia, 474; separation of child from parents by, 100
Host, **266**
Hostages, posttraumatic stress disorder among, 147–48, 149
Hostility (*see* Aggression; Delinquency)
HRSD (Hamilton Rating Scale for Depression), 578

Human immunodeficiency virus infection (*see* Acquired immunodeficiency syndrome (AIDS))
Humanistic-experiential therapies, **650–54**; client-centered, 650–52; evaluation of, 654; existential, 652–53; gestalt, 653
Humanistic perspective, **89–92**; impact of, 92; self-concept and, 91; values and personal growth and, 91–92
Humanitarian approach, 39–48; early asylums and shrines and, 41–42; resurgence of scientific questioning in Europe and, 40–41; treatment reforms based on, 42–48
*Human Sexual Inadequacy* (Masters and Johnson), 437–38
Huntington's disease, 496
Hurricane Hugo, 136
Hydrocephalus, **514**
Hydrophobia, 161
Hyperactivity (*see* Attention-deficit hyperactivity disorder (ADHD))
Hyperesthesia, in conversion disorder, 260
Hyperkinesis, treatment for, 617–18
Hyperobesity, 389–92; causes of, 389–91; treatment for, 391–92
Hypertension, **297–98**
Hyperventilation, for panic disorder, 194
Hypesthesia, in conversion disorder, 260
Hypnosis, 40, 53–54; conversion disorder and, 260; hysteria and, 54; in psychotherapy, 633; for treatment of dissociative identity disorder, 275
Hypoactive sexual desire disorder, **431**
Hypochondriasis, **255–57**
Hypofrontality, in schizophrenia, 467–68
Hypomania, **209**
Hypothalamic-pituitary-adrenal axis: in bipolar mood disorders, 233; in unipolar mood disorders, 215
Hypothalamic-pituitary-thyroid axis: in bipolar mood disorders, 233; in unipolar mood disorders, 215
Hypothalamic-pituitary-adrenocortical axis, physical illness and, 286
Hypotheses, **19–20**; development of, 569
Hypoxia, mental retardation and, 510
Hysteria, 253 (*see also* Conversion disorder); hypnosis and, 54; mass, 37–38, 262

ICD (International Classification of Diseases), 12, 696
Id, 79
Identification, as defense mechanism, 80
Identity (*see also* Dissociative identity disorder (DID)); in borderline personality disorder, 323; confusion about, in schizophrenia, 451; gender, disorders of, 414–16
IDRA (Insanity Defense Reform Act) of 1984, 688, 689
Imaging, of brain, 571–72
Imipramine (Tofranil), 613; for childhood depression, 547; for depression, 661; for enuresis, 549; for mood disorders, 236; for panic attacks, 172; for panic disorder, 614
Immune system, 283–87, **284;** components of, 284–85; psychosocial factors and, 285–87
Impact of Events Scale, 126
Impact phase, in coping with rape, 139
Implicit memory, **263**
Implicit perception, **263**
Implosive therapy, **637**, 638
Impotence, 432, 435; treatment for, 438–39
Impulsive behavior, in antisocial personality disorder, 338
Inadequate parenting, 101–3; alcohol abuse and, 366; conduct disorders and, 536–37; overanxious anxiety disorder and, 544
Incest, **423–24**
Incidence, **17**
Inderal, for social phobias, 191
Index case, 72
India, schizophrenia in, 473
*Indian Medical Gazette,* 609
*I Never Promised You a Rose Garden* (Green), 5
Infants, premature, 74–75; mental retardation and, 510
Influenza, schizophrenia and, 468
Insanity, **34**
Insanity defense, 153, **687–89**, 699; psychological tests and, 590
Insanity Defense Reform Act (IDRA) of 1984, 688, 689
Inspectionalism, 409–10
Institute of Juvenile Research, 56
Institutionalization, 98–99 (*see also* Hospitalization); for Alzheimer's disease, 501–2; of children and adolescents, 557–58; clinical assessment and, 578; deinstitutionalization and, 689–93; for mental retardation, 516–17
Instrumental conditioning, **57, 84** (*see also* Operant conditioning)
Insulin coma therapy, **603**
Integrative Strategy Instruction (ISI), 522
Intellectualization, as defense mechanism, 80
Intelligence and IQ scores (*see also* Mental retardation); in attention-deficit hyperactivity disorder, 531; cultural-familial retardation and, 514–16, 522–23; nutritional deficiencies and, 77
Intelligence tests, 579; culture-free, 523; in mental retardation, 507
Internal reinforcement, 88
International Classification of Diseases (ICD), 12, 696
International mental health efforts, 695–96
Interoceptive conditioning, 173–74; for anxiety disorders, 193
Interoceptive fears, **173–74**
Interpersonal accommodation, **94**
Interpersonal perspective, **92–95**; communication and interpersonal accommodation and, 94; impact of, 94–95; social exchange and roles and, 94; Sullivan's theory and, 93–94
Interpersonal relationships: alcohol abuse and, 367–68; in antisocial personality disorder, 338–39; parental, delinquency and, 541; physical illness and, 302–3; in schizophrenia, 457; sexual dysfunctions and, 436–37; therapeutic, 628–30; therapy for, 654–58
Interpersonal therapy (IPT), 94–95, 635, 661; for mood disorders, 238, 239
Interviews, assessment, 574–75, 576, 577
Intracranial hemorrhage, 503
Intrapsychic conflicts, **79**
Introjection, **82**
In vitro procedures, 637–38
Ionizing radiation, mental retardation and, 510
IPT (interpersonal therapy), 94–95, 635, 661; for mood disorders, 238, 239
IQ (*see* Intelligence and IQ scores; Intelligence tests)
Irresistible impulse rule, 688
Irresponsible behavior, in antisocial personality disorder, 338
ISI (Integrative Strategy Instruction), 522
Isocarboxazid (Marplan), 612

Isolation: as defense mechanism, 80; in obsessive-compulsive disorder, 185–86
Israeli-NIMH High-Risk Study, 464
Italy, exaggeration of physical complaints in, 109

Jamaica, overcontrolled problems in, 109
Japan: physical illness in, 304; suicide in, 244
Jealous delusional disorder, 476
Jenkins Activity Survey for Health Prediction, 289
*Journal of Abnormal Psychology,* 23, 56, 226
Judgment, brain damage and, 487

Malaria, false, in conversion disorder, 262
Malarial treatment, for syphilis, 50, 51
Malaysia, schizophrenia in, 473
Male erectile disorder, **432**
Male orgasmic disorder, **433**
Malingering, **254,** 263, 698–99; conversion reactions versus, 262; dissociative identity disorder versus, 268
*Malleus maleficarum,* 40
Malnutrition, 76–77; eating disorders and, 296; mental retardation and, 510
Mania, **201;** in bipolar disorder, 210–11; dancing, 37, 40; treatment for, 233, 617, 620 (*see also* Lithium)
Manic-depressive insanity (*see* Bipolar disorder)
Manifest content, **633**
MAO (monoamine oxidase) inhibitors, 612, 613; for generalized anxiety disorder, 614; for personality disorders, 335; for social phobia, 191
Maprotiline (Ludiomil), 613
Marijuana, **386;** abuse and dependence on, 386–88
Marital discord, 103 (*see also* Divorce); alcohol abuse and, 367–68; depression and, 208–9, 230, 240; physical illness and, 302; schizophrenia and, 471; sexual dysfunctions and, 436–37; transvestic fetishism and, 408–9
Marital schism, **471**
Marital separation, stress from, 134
Marital skew, **471**
Marital status, depression and, 236
Marital therapy, **654–56;** for mood disorders, 240
Marplan (isocarboxazid), 612
Masculinity, role expectations and, 111
Masochism, **412,** 413–14
Mass hysteria, 37–38, 262
Mass murders, 137
Masturbation, 402; sexual behavior and, 401
MBD (minimal brain dysfunction), 521
MCLP (mesocorticolimbic dopamine pathway), psychoactive substance abuse and, 364, 365
*Medical Inquiries and Observations upon the Diseases of the Mind* (Rush), 44
Medical model (*see* Biological perspective; Biological therapy)
Medications (*see* Pharmacologic therapy)
Medroxyprogesterone acetate (MPA; Depo-Provera), for sex offenders, 430
Melancholic major depression, **207**
Melanesia, homosexuality in, 402
Mellaril (thioridazine), 610, 611
*Memmel* v. *Mundy,* 682

Memory(ies) (*see also* Amnesia); in Alzheimer's disease, 497; brain damage and, 487; of childhood trauma, 271, 272–73; of children, reliability of, 420–21; electroconvulsive therapy and, 605; false, 271, 439; hypnosis to facilitate recall of, 633; implicit, 263; of sexual abuse, 418, 420–21, 422
Men and boys (*see also* Gender *entries;* Masculinity); gender identity disorders in, 414–16; homosexual (*see* Homosexuality); Oedipus complex and, 81–82; rape and (*see* Rape); sexual dysfunctions of, 432, 433, 434–39; sexual variants and, 407–11, 413–14
Mental health: changing attitudes toward, 49–50; future challenges for, 696–700; government efforts for, 693–94; international efforts for, 695–96; private industry resources and, 695; professional organizations and, 694; voluntary mental health organizations and agencies and, 694–95
Mental health profession(s), 10–11 *(see also specific professions)*
Mental health professionals *(see also* Therapists; *specific professions);* consultation and education and, 676; providing psychotherapy, 627–28; Victorian, 47–48
Mental hospitals (*see also* Hospitalization; Institutionalization); before antipsychotic drug therapy, 609; conditions in, 5–6; deinstitutionalization and, 689–93; early, 41–46; first, 35; patient rights and, 682; as therapeutic communities, 678–80; token economies in, 641–42; Victorian, 47–48, 49–50
Mental hygiene movement, **45–46,** 48
*Mental Maladies* (Esquirol), 43
Mental retardation, **506–509**; assessment in, 516; brain defects in, 509–10; cranial anomalies associated with, 513–14; cultural-familial, 514–16, 522–23; defining, 507–8; Down syndrome and, 71, 500, 509, 510–13; levels of, 507–9; phenylketonuria as cause of, 71, 513; prevention of, 518–19; treatment for, 516–18
Mental status exam, 574
Meprobamate (Equanil; Miltown), 614
Mescaline, **386;** abuse and dependence on, 386
Mesmerism, **53–54**
Mesocorticolimbic dopamine pathway (MCLP), psychoactive substance abuse and, 364, 365
Methadone, **380**–81
Methylphenidate (Ritalin), 617–18; for attention-deficit hyperactivity disorder, 534
Metrazol, convulsions induced by, 603
Microcephaly, **514**
Middle Ages: resurgence of scientific questioning during, 40–41; views of abnormal behavior during, 35–39, 58, 60
Migraine, **298–99**, 300
Mild disorders, **16**
Mild mental retardation, 508
Milieu therapy, 609, **678–80**
Militaristic regimes, vulnerability to disorders and, 112
Military combat *(see* Combat *entries)*
Miltown (meprobamate), 614
*A Mind That Found Itself* (Beers), 5, 49
Minimal brain dysfunction (MBD), 521
Minnesota Multiphasic Personality Inventory (MMPI), 581, **583**–89; coronary heart disease and, 291; in forensic cases, 589, 590; scales of, 583, 585
Minor tranquilizers (*see* Antianxiety drugs; Benzodiazepines)
Mixed delusional disorder, 476
MMPI (*see* Minnesota Multiphasic Personality Inventory (MMPI))
MMPI-2 (*see* Minnesota Multiphasic Personality Inventory (MMPI))
M'Naughten Rule, 688–89
Modeling, **640–41**; shaping of desired behavior and, 86; participant modeling, 195
Models (*see specific perspectives, i.e.* Biological perspective)
Moderate disorders, **16**
Moderate mental retardation, 508
Monoamine hypothesis: of bipolar disorders, 232; of unipolar mood disorders, 214–15
Monoamine oxidase, 612
Monoamine oxidase (MAO) inhibitors, 612, 613; for generalized anxiety disorder, 614; for personality disorders, 335; for social phobia, 191
Monophobia, 161
Mood-congruent delusions, **207**
Mood disorders, 199–240 (*see also* Depression); bipolar (*see* Bipolar disorders; Cyclothymia); causes of, 213–36; comorbidity of, 229, 324; interpersonal effects of, 228, 230–31; medical conditions as cause of, 200; substance-induced, 200; treatment for, 236–40; unipolar, 200, 201 (*see also* Adjustment disorder; Dysthymia; Major depressive disorder)
Mood-incongruent delusions, **207**
Mood neuropsychological syndromes, 492–93
Moral anxiety, 79
Moral management, **44–45**, **46**
Morbid obesity (*see* Hyperobesity)
Mormons, alcohol abuse among, 368–69
Morphine, **375**
Motor symptoms: in conversion disorder, 260, 261; in schizophrenia, 451, 454–56
"Mourning and Melancholia" (Freud), 222
MPA (medroxyprogesterone acetate), for sex offenders, 430
MPD (*see* Dissociative identity disorder (DID))
MRI (nuclear magnetic resonance imaging), 572–73
Multi-infarct dementia, 502
Multimodal therapy, for anxiety disorders, 193, 195
Multiple personality disorder (MPD) (*see* Dissociative identity disorder (DID))
Mundugumor, 110
Muslims, alcohol abuse among, 368–69
Mutism, 260
Myocardial infarction, 290
Mysophobia, 161

NAMH (National Association for Mental Health), 694
Nancy School, **54**
NARC (National Association for Retarded Citizens), 694–95
Narcissistic personality disorder, 317, **321–22**, 329; causes of, 331–32
Narcolepsy, treatment for, 384
Narcotic abuse and dependence, 375–81; causes of, 379–80; effects of, 378–79; heroin and, 375–77, 378–79; morphine and, 375, 378–79; treatment for, 380–81
Narcotics subculture, 380

Nardil (phenelzine), 612; for posttraumatic stress disorder, 152
National Association for Mental Health (NAMH), 694
National Association for Retarded Citizens (NARC), 694–95
National Center for Child Advocacy, 562
National Committee for Mental Hygiene, 694
National Institute for Occupational Safety and Health (NIOSH), 695
National Institute of Mental Health (NIMH), 693–94; Consensus Development Conference of on ECT, 605; Epidemiologic Catchment Area program of (*see* Epidemiologic Catchment Area (ECA) study); on prevalence of mental disorders, 17–18; study of treatment of depression sponsored by, 661
National Institute on Alcohol Abuse and Alcoholism (NIAAA), 693
National Institute on Drug Abuse (NIDA), 693–94
National Mental Health Foundation, 694
National Organization for Mentally Ill Children, 694
Native Americans: alcohol abuse among, 365–66; physical illness among, 304
Navajo Indians, physical illness among, 304
Needs, physiological, 76–77
Negative automatic thoughts, **223**
Negative cognitive triad, **223–24**
Negative-symptom schizophrenia, **448**
Neglecting-uninvolved parenting style, 103
Neurasthenia, 47–48
Neuroanatomical factors, in schizophrenia, 467–69
Neurobiological causal factors, for panic disorder, 172–73
Neuroendocrine factors, in unipolar mood disorders, 215; in bipolar mood disorder, 233
Neurofibril tangling, 499
Neurological examination, 571–72
Neurophysiological factors, in unipolar mood disorders, 215–16
Neuropsychological assessment, **572–74**, 589
Neuropsychological disorders, 486–90; clinical features of, 488–90; diagnosis of, 490; hardware and software and, 487–88; with HIV infection, 493–95; neuropsychology/psychopathology interaction and, 487; in schizophrenia, 466–67
Neuropsychological symptom syndromes, 490–93
Neurosis, **157–58**; transference, 634
Neurosurgery, 606–8
Neurosyphilis (*see* Syphilis)
Neurotic anxiety, 79
Neurotic behavior, **157**
Neuroticism, **271**; physical health and, 282; unipolar mood disorders and, 220
Neurotransmitters, **69**, 70; in Alzheimer's disease, 499, 501; in bipolar disorders, 232; generalized anxiety disorder and, 181; in obsessive-compulsive disorder, 189; in schizophrenia, 465–66; in unipolar mood disorders, 214–15, 216–17
New Haven-Baltimore-St. Louis Epidemiologic Catchment Area (ECA) program (*see* Epidemiologic Catchment Area (ECA) study)
N=1 experiments, **24**
NGRI (not guilty by reason of insanity), 687–89, 699
NIAAA (National Institute on Alcohol Abuse and Alcoholism), 693
Nicotine, abuse and dependence on, 388–89
NIDA (National Institute on Drug Abuse), 693–94
Niemann-Pick's disease, 511
Nightmares, following disasters, 137
NIMH (*see* National Institute of Mental Health (NIMH))
NIOSH (National Institute for Occupational Safety and Health), 695
Nocturnal panic, 169
Nondirective therapy, 650–52
Nonshared environmental influences, 73
Norepinephrine: alarm reaction and, 130; in bipolar disorders, 232; panic disorder and, 172–73; in unipolar mood disorders, 214–15
North Karelia Project, 308–9
Nortriptyline (Aventyl), 613
Not guilty by reason of insanity (NGRI), 687–89, 699
Not-me, 94
Nuclear accidents, stress caused by, 123, 124
Nuclear magnetic resonance imaging (MRI), **572–73**
Nutrition (*see* Diet; Malnutrition)
Nyctophobia, 161

Obesity (*see* Hyperobesity)
Objective personality tests, 582–89
Object-relations concept, 82
Observation: clinical, 575–79; in research, 19–20
Observational learning, 640–41; of phobias, 163
Obsessive-compulsive disorder (OCD), **182**–90; causes of, 185–86, 188–90; cognitive and motor patterns in, 184; treatment for, 187, 193, 614, 638
Obsessive-compulsive personality disorder, 317, **326–27**, 327–28, 329
Occipital damage, 490
Occupation, stress and, 121–22
Occupational therapists, 628
OCD (*see* Obsessive-compulsive disorder (OCD))
Ochlophobia, 161
Oedipus complex, **81–82**
Oedipus conflict, 107
*Onania, or the Heinous Sin of Self-Pollution,* 401
*One Flew Over the Cuckoo's Nest* (Kesey), 5, 604
*On Sacred Disease* (Hippocrates), 33
*On the Physical Mechanisms of Hysterical Phenomena* (Freud and Breuer), **55**
Operant conditioning, **57, 84**–85; biofeedback and, 643; of illnesses, 303–4
Operational fatigue, 141
Opiates (*see* Endorphins; Narcotic abuse and dependence)
Opium, **375**
Oppositional defiant disorder, 345, **535**
Optimism, physical health and, 281
Oral stage, 81; regression to, 222
Organic mental disorders, **486** (*see also* Neuropsychological disorders); caffeine-induced, 388; nicotine-induced, 388
Orgasm, **431**; disorders of, 433–34, 438
Orientation, brain damage and, 487
*Osherhoff* v. *Chestnut Lodge,* 618
Out-of-body experiences, 269
Overanxious anxiety disorder, **544**
Overcompensation, as defense mechanism, 80
Overgeneralization, 224
Oxazepam (Serax), 614

Pain: in chest, 290; headaches, 298–300
Pain disorder, **257**–58
Panic, **158**

Panic attacks, 169, 171–72; pharmacological provocation of, 172; treatment for, 172
Panic disorder, **168–76**; agoraphobia and, 169; causes of, 172–76; obsessive-compulsive disorder with, 184; treatment for, 191, 194, 614, 638
Panic provocation agents, 172
Paradigm shifts, 67
Paralysis, hysterical, 260
Paranoia, **443**, **475** (*see also* Delusional disorder); in Alzheimer's disease, 498
Paranoid disorder (*see* Delusional disorder)
Paranoid personality disorder, **316–18**, 329
Paranoid schizophrenia, 453, **457**–59
Paraphilais, pedophilia, 422–23
Paraphilias, **404,** 406–14; autogynephilia, 416; causes of, 413–14; exhibitionism, 410–11; fetishism, 407–9; masochism, 412; rape as, 427–28; sadism, 411–12; voyeurism, 409–10
Paraprofessionals, providing psychotherapy, 628
Parent(s): abusive, 99, 560; antisocial, delinquency and, 541; of autistic children, treatment contracts with, 555; as change agents, 557; communication with, 103; with emotional disorders, 562–63; psychopathology in, 101; single, 104; treatment of, 557; treatment of conduct disorders and, 537
Parental control, 102–3
Parental deprivation, 98–99, 100; antisocial personality disorder and, 344; delinquency and, 540; unipolar mood disorders and, 221
Parental rejection: antisocial personality disorder and, 344–45; delinquency and, 540–41
Parental warmth, 102–3
Parent-child relationship: childhood depression and, 547; vulnerability to depression and, 222
Parent education, for drug and alcohol abuse prevention, 672
Parenting: inconsistent, antisocial personality disorder and, 344–45; schizophrenogenic, 470–71
Parenting styles, 101–3
Paresthesia, in conversion disorder, 260
*Paris Is Burning* (film), 416
Parkinson's disease, 493
Parnate (tranylcypromine), 612
Paroxetine (Paxil), 621
Passive-aggressive personality disorder, 317, **328,** 329
Passive avoidance learning, in antisocial personality disorder, 342
Path analysis, 21–22
Pathogenic families, 103–4, 556–57, 562–63 (*see also* Divorce); alcohol abuse and, 368; attention-deficit hyperactivity disorder and, 532; conduct disorders and, 536–37; delinquency and, 540–41; depression and, 230; eating disorders and, 293, 296, 303; physical illness and, 303; schizophrenia and, 470–71; therapy for, 656–59
Pathological gambling, **392–96**; causes of, 394–95; clinical picture in, 393–94; treatment for, 395–96
*The Pathology and Therapy of Psychic Disorders* (Griesinger), 50
Pathophobia, 161
Patient, use of term, 17
Patient advocacy, 682
Paxil (paroxetine), 621
Pedigree, 72
Pedophilia, **422–23**
Peer group influence programs, for drug and alcohol abuse prevention, 672–73
Peer relationships: child abuse and, 561; delinquency and, 542; maladaptive, 104–6; popularity versus rejection and, 105–6
Penile plethysmography, 422
Penile prostheses, 438
Pennsylvania Hospital, 42, 44
Perception: disruption of, in schizophrenia, 450–51; implicit, 263; of stress, 122–23, 124
Permissive-indulgent parenting style, 102–3
Perphenazine (Trilafon), 610
Persecutory delusional disorder, 475–76
Personal constructs, 87–88
Personal growth, humanistic perspective and, 91–92
Personality: alcohol abuse and, 365, 366–67; borderline, 82, 323; combat stress and, 144; dissociative identity disorder and, 264, 266–68; executive branch of, 79; headaches and, 300; hypertension and, 298; interpersonal theory of, 93–94; pharmacologic treatment and, 621; phobias and, 165; physical illness and, 288–92; psychogenic physical illness and, 302; unipolar mood disorders and, 220
*Personality and Psychotherapy* (Dollard and Miller), 85, 658
Personality disorders, 312–52, **313** (*see also specific personality disorders,* e.g., Antisocial personality disorder); causes of, 330–32; clinical features of, 314–16; comorbidity of, 324, 330; diagnosis of, 315, 349–51; drug abuse and dependence and, 379; treatment for, 332–35; types of, 316–30
Personality tests, 579–89; in forensic cases, 589, 590; objective, 582–89; projective, 580–82
Person-centered therapy, **650–56**
Personifications, 94
Personnel screening, psychological tests in, 590–92
Pessimistic attributional style, **221**
Petechial hemorrhage, 503–4
PET (positron emission tomography) scans, 571–73; in bipolar mood disorders, 233
Phallic stage, 81
Pharmacists, narcotic dispensing and, 378
Pharmacologic therapy, 608–21; for AIDS, 494; for alcohol abuse, 371; for alcohol withdrawal, 362–63, 369–70; for Alzheimer's disease, 499, 501; for antisocial personality disorder, 347; for anxiety, 181; for anxiety disorders, 190–91; for attention-deficit hyperactivity disorder, 532–33, 534; for autism, 554; biopsychosocial perspective on, 618–21; for children, 545, 547, 617–18; for delusional disorder, 481; for depression, 547; for drug withdrawal, 380–81; for enuresis, 549; for headaches, 299; for hyperobesity, 391; for mood disorders, 236–38; for nicotine withdrawal, 389; for panic attacks, 172; for personality disorders, 335; for posttraumatic stress disorder, 152; during pregnancy, mental retardation and, 509; for psychogenic physical illness, 305–6; right to refuse, 682; for schizophrenia, 465, 466, 474; for sex offenders, 429–30; for sleepwalking, 550; for somato-

form disorders, 274; for stimulant abuse, 383, 384; types of drugs used in, 608–17
Pharmacology, **608**
Phenelzine (Nardil), 612; for posttraumatic stress disorder, 152
Phenothiazines, 609–11; for schizophrenia, 474
Phenotype, 71–72
Phenylalanine, 71
Phenylketonuria (PKU), 71, 513
Phobias, **160**–76; agoraphobia, 160, 169–76, 191; avoidance behavior and, 173; behavioral techniques used with, 86; causes of, 163–66, 167–68; obsessive-compulsive disorder with, 184; preparedness theory of, 165–66, 167–68; among rape victims, 140; social, 166–68, 184; specific, 160–66; treatment for, 638
Physical assessment, 570–74; general physical examination and, 571; neurological examination and, 571–72; neuropsychological examination and, 572–74
Physical deprivation, 76–78
Physical handicaps, 76; as constitutional liability, 73–75
Physical health and illness, 278–311 (*see also* Somatoform disorders); AIDS and, 309–10; anorexia and bulimia and, 292–97; causes of psychogenic illnesses and, 300–305; coronary heart disease and, 288–92; depression and, 76; headaches and, 298–300; hypertension and, 297–98; psychogenic, 279–80; psychological factors in, 281–88; treatments for illness and, 305–9
Physicians (*see also* Psychiatrists); narcotic dispensing and, 378; providing psychotherapy, 627
Physiological changes, associated with stress, 130–31
Physiological needs, 76–77
Pick's disease, 496
PKU (phenylketonuria), 71, 513
Placebo effect, **282**
Plane crashes, 135, 136–37, 151, 154; secondary prevention for survivors of, 676–78
Planning, need for, 697
Play therapy, 546, 557; for childhood depression, 548
Pleasure principle, 79
Popularity, 105–6
Positive affect, 229
Positive reinforcement, **86**
Positive-symptom schizophrenia, **448**
Positron emission tomography (PET) scans, **571–73**; in bipolar mood disorders, 233
Possession (*see* Demonology)
Postconcussional disorder, 504
Posthypnotic suggestions, 633
Postpartum depression, 203, 204
Posttraumatic recoil phase, in coping with rape, 139
Posttraumatic stress disorder (PTSD), **134–35**, 135–50, 152–53; causes of, 138; child abuse as, 560; combat and (*see* Combat stress); forced relocation and, 148–50; among hostages, 147–48, 149; physical illness and, 287; politics of, 153–54; among prisoners of war and concentration camp survivors, 145–47; rape and, 138–40, 426; among torture victims, 148, 149; treatment for, 152–53
Poverty (*see* Socioeconomic status)
POWS (*see* Prisoners of war (POWs))
Predictability, lack of, anxiety and, 179–80
Prefrontal lobotomy, **606**, 607
Pregnancy (*see also* Prenatal development); false, in conversion disorder, 262
Prejudice, 112–13
Premature ejaculation, 400, **433**
Prematurity, 74–75; mental retardation and, 510
Prenatal conditions, as constitutional liabilities, 75
Prenatal development: cocaine and, 382; fetal alcohol syndrome and, 75, 361; mental retardation and, 509, 510
Preparedness theory of phobias, 165–66, 167–68
Presenile dementias, **495**, 496
President's Commission on Mental Health, 561
Presynaptic neurons, 69, 70
Prevalence, **17**; lifetime, 17–18
Prevention, 668–81; of child abuse, 560–61; of mental retardation, 518–19; primary, 668–74; secondary, 668, 674–78; of stress, 152; of suicide, 246–49, 250; tertiary, 668, 678–81
Priests, pedophilia and, 423
Primary prevention, **668**–74; biological, 669–70; of drug and alcohol use, 671–74; psychosocial, 670; sociocultural, 670–71
Primary process thinking, **79**
Primary reaction tendencies, 75
Prisoners of war (POWs): apathy deaths among, 282; dietary deficiencies suffered by, 77; posttraumatic stress disorder among, 145–46
Private industry, mental health resources in, 695
Proband, 72
Probation, for delinquency, 542–43
Problem identification, 568–69
Process schizophrenia, **448**
Prochlorperazine (Compazine), 610
Professional journals, 23, 56, 226, 280, 609
Professional organizations, 694
Profound mental retardation, 509
Project Head Start, 519, 523
Projection, as defense mechanism, 80
Projective tests, 580–82
Project Northland, 671–72
Prolixin (fluphenazine), 610
Promazine (Sparine), 610
Propanediols, 614
Prospective research, **24–25**
Protective factors, primary prevention and, 668–69
Prototypal approach, **27–28**
Prozac (*see* Fluoxetine (Prozac))
Pseudodementia, 493
Psilocybin, **386**; abuse and dependence on, 386
Psychedelic drugs, abuse and dependence on, 376–77, 385–86
Psychiatric Foundation, 694
Psychiatric nurses, 628
Psychiatric nursing, **10–11**, 628
Psychiatric social work, **10**
Psychiatric social workers, **627**, 628
Psychiatrists, **627**, 628

Schemas, 89, 95–98, **96**
Schizoaffective disorder, **212, 459**
Schizoid personality disorder, 317, **318**–19, 329
Schizophrenia, **443,** 444–75; autonomic nervous system impairment and, 22; birth complications and, 22; borderline, 323; causes of, 459–74; clinical picture in, 448–51; defining, 451–52; diagnosis of, 12, 450, 481–82; in Genain quadruplets, 445–48; socioeconomic status and, 111; subtypes of, 452–59; treatment for, 448, 465, 466, 474–75, 476, 603; twin studies of, 73; unresolved issues concerning, 481–82
Schizophrenia scale, on MMPI, 583
Schizophrenics Anonymous, 475
Schizophreniform disorder, 454, **459**
Schizophrenogenic parenting, **471–72**
Schizotypal personality disorder, 317, **319–20**; schizophrenia and, 468; treatment for, 335
School psychologists, 628
Scientific journals, 23, 226, 280, 609; origin of, 56
Scotophilia, 409–10
Seasonal affective disorder, **209,** 216–17
Seasonal bipolar disorder, 211–12
Season of birth effect, schizophrenia and, 468–69
Secondary gains, **258–59, 304**
Secondary prevention, **668,** 674–78; for airplane crash survivors, 676–78; consultation and education of intermediaries and, 676; crisis intervention and, 674–76
Secondary process thinking, **79**
Sedatives, abuse and dependence on, 376–77, 384–85
Selective abstraction, 223
Selective serotonin re-uptake inhibitors (SSRIs), 613; for mood disorders, 237
Self-actualization, **92**
Self-concept, humanistic perspective and, 91
Self-control training, for alcohol abuse, 371
Self-esteem, programs to increase, 673
Self-identity, 96
Self-monitoring, **575**
Self-mutilation, in borderline personality disorder, 323
Self-report inventories, 583–89
Self-schemas, 95–98, **96**
Self-stimulation, in autism, 553
Self-system, 93–94

Semen conservation, 402
Senile dementias, **495** (*see also* Dementia of the Alzheimer's type (DAT))
Senile plaques, 499–500
Sensory symptoms, in conversion disorder, 260, 261
Sentence-completion test, **582**
Separation: of children from parents, 98–99, 100; marital (*see* Marital separation)
Separation anxiety disorder, **543–44**
Separation-individuation, 82
Serax (oxazepam), 614
Serotonin: in bipolar disorders, 232; in obsessive-compulsive disorder, 189; in unipolar mood disorders, 214–15
Sertraline (Zoloft), 621
*Sesame Street* (television program), 519
Severe discipline, 102
Severe disorders, **16**
Severe major depressive episode with psychotic features, **206–7**
Severe mental retardation, 508–9
*Sex and Repression in Savage Society* (Malinowski), 107
Sex-change surgery, 416
Sex chromosomes, 71
Sex offenders: rapists, 427–28; treatment and recidivism of, 428–30
Sexual abuse, **399–400**, 416–30; of children, 417–23, 439–40, 559–60; incest and, 423–24; long-term consequences of, 439–40; pedophilia and, 422–23; as posttraumatic stress disorder, 560; rape (*see* Rape); treatment for, 428–30
Sexual aversion disorder, **431–32**
Sexual behavior (*see also* Sexual variants); sociocultural influences on, 400–404; by therapist, 663–64
Sexual dysfunctions, 400, **430–39**; causes of, 434–37; orgasmic disorders, 431, 433–34; of sexual arousal, 431, 432–33; of sexual desire, 431–32; sexual pain disorders, 431, 434; treatment for, 437–39
Sexual variants, 399, 404, 406–16; causes of, 413–14; gender identity disorders, 414–16; paraphilias, 404, 406–14
Shaping, of responses, 641
Shaping of desired behavior, **86**
Shared environmental influences, 73
Shared psychotic disorder, **475** (*see also* Delusional disorder)
Shell shock, 140
Shi'ite Muslims, grief among, 109
Shock stage, of disaster syndrome, 135
Short-term crisis therapy, **674, 675**
Simple phobias, 160–66
Simple tension headaches, **299**
Single-parent households, 104
Skills-training procedures, for alcohol abuse, 371
Sleep (*see also* Rapid-eye-movement (REM) sleep); deprivation of, 76; disturbances of, in unipolar mood disorders, 216
Sleep medications, 615
Sleepwalking disorders, **549**; during childhood, 549–51
Smoking, 388–89
Smooth pursuit eye movement (SPEM), in schizophrenia, 466
*The Snake Pit* (Ward), 5
Snakeroot, 609
Social change, vulnerability to disorders and, 113
Social context, assessment of, 569
Social-exchange view, **94**
Social interaction, alcohol abuse and, 367
Socialization, interpersonal theory of personality and, 93–94
Social-learning programs, **679**
Social phobia, 166–68; obsessive-compulsive disorder with, 184; treatment for, 191, 193, 638
Social Readjustment Rating Scale, 126
Social roles, 94; disorder-engendering, 112
Social-skills training: for schizophrenia, 475; for sex offenders, 429
Social supports, stress and, 123–24
Social values, psychotherapy and, 662–63
Society for the Suppression of Vice, 401–2
Sociocultural causal factors, 110–13; for alcohol abuse, 368–69; for antisocial personality disorder, 346; for anxiety disorder, 189–90; for autism, 554; for bipolar disorders, 235–36; for combat stress, 144–45; cross-cultural studies of, 106–10; for delinquency, 542; for drug abuse and dependence, 380; for hyperobesity, 390–91; for personality disorders, 332; primary prevention and, 670–71; for psychogenic physical illness, 304–5; for schizophrenia, 472–74; sexual practices and standards and, 400–404; for somatoform and dissociative, 274; for suicide, 244–45; for unipolar mood disorders, 235–36
Sociocultural environment, 110–11
Sociocultural perspective, 106–10
Sociocultural treatment measures, for psychogenic physical illness, 308–9
Socioeconomic status: delinquency and, 104; divorce and, 104; hyperobesity and, 390–91; low, as pathogenic influence, 111
Sociopathy, 335
Sociotropy, unipolar mood disorders and, 220
Sodium lactate, panic attacks and, 172
Somatic delusional disorder, 476
Somatization disorder, **254–55**
Somatoform disorders, **253**, 254–63; causes of, 269–74; conversion disorder, 258–63; hypochondriasis, 255–57; pain disorder, 257–58; somatization disorder, 254–55; unresolved issues concerning, 275–76
Somnambulism, during childhood, 549–51
*Soroka* v. *Dayton-Hudson*, 591
*Souder* v. *Brennan*, 682
Sparine (promazine), 610
Specific learning disorders, **519–23**; causes of, 520–22; clinical picture in, 520; delinquency and, 540; treatment for, 522, 617–18
Specific phobias, **160–66**; social, 166
Speech: in autism, 552; in catatonic schizophrenia, 455; in conversion disorder, 260
Speed, 383
SPEM (smooth pursuit eye movement), in schizophrenia, 466
Splitting: as defense mechanism, 80; treatment of borderline personality disorder with, 334
Spontaneous recovery, **84**
SSRIs (selective serotonin re-uptake inhibitors), 613; for mood disorders, 237
*Staff* v. *Miller*, 682
Stanford-Binet Intelligence Scale, 579
Statistical controls, 24
Stelazine (trifluoperazine), 610
Stimulant drugs, 620; abuse and dependence on,

376–77, 381–84; for antisocial personality disorder, 347; for attention-deficit hyperactivity disorder, 532–33, 534
Stimulation: electrical, as therapy, 602; need for, 77–78; seeking of, in antisocial personality disorder, 343; of self, in autism, 553
Stimulus: conditioned, 84; unconditioned, 84
Stonewall riot, 404
Stress, 119–54, **120** (*see also* Posttraumatic stress disorder (PTSD); Stressors); acute, 134–35; adjustment disorder and, 131–34; alcohol abuse and, 367; from bereavement, 133–34; bipolar disorders and, 233–34; catastrophic events and, 135–38; combat and (*see* Combat stress); coping strategies and, 120, 126–31; divorce and, 123; from divorce or separation, 134; executive, decomposition under, 128–31; factors predisposing to, 122–26; headaches and, 300; immune function and, 285, 287; perception and tolerance of, 122–23, 124; physical health and, 282; physiological changes associated with, 130–31; prevention or reduction of, 152; reduction of, 307–8; schizophrenia and, 472; treatment for, 150–53; from unemployment, 131–33; unipolar mood disorders and, 217–20
Stress-inoculation therapy, **646**–47, 649
Stress-inoculation training, **152**
Stressors, **120** (*see also* Stress); categories of, 120–22; DSM-IV and, 131; nature of, 122
Stress tolerance, **123**
Striatum, in obsessive-compulsive disorder, 188–89
Structural Analysis of Social Behavior, 293
Structural family therapy, 657–58
Stupor, in catatonic schizophrenia, 454–55
Subculture, narcotics, 380
Subdural hematoma, 503
Subgroups, 111
Sublimation, as defense mechanism, 80
Substance abuse (*see* Alcohol abuse and dependence; Drug abuse and dependence)
Sudden cardiac death, 290
Suggestible stage, of disaster syndrome, 135–36
Suicide, 202, **240**–50; alcohol abuse and, 356, 357; ambivalence about, 245–46; appraisal for, 548; in borderline personality disorder, 323; people committing, 241–43; prevention of, 246–49, 250; psychosocial factors associated with, 243–45; warning signs for, 243
Suicide notes, 246, 247
Superego, 79
Superstition, 32–33, 37, 38–39
Support groups, for Alzheimer's disease, 501
Suppressed-rage hypothesis, of hypertension, 298
Surgery: psychosurgery, 606–8; transsexual, 416
Suspiciousness, in schizophrenia, 457
Sybil, 270–71
Symptom/underlying cause point of view, 52
Syndrome, **9**
Syphilis, 76; discovery of organic factors underlying, 50, 51
Systematic desensitization, 89, **638**–39; for anxiety disorders, 192

Tacrine (Cognex), for Alzheimer's disease, 499, 501
Taijan kyofusho (TKS), 108, 189–90
Take Off Pounds Sensibly (TOPS), 391
Tantrums, behavior-modification techniques used with, 86
Tarantella, 37
Tarantism, **37**
Tarasoff decision, **686**–87
Tardive dyskinesia, **610**–11
Target dosing, 611
Task-oriented response, **127**
TAT (Thematic Apperception Test), 580, 581–82
Tay-Sachs disease, 511
TCAs (tricyclic antidepressants), 612–13
Team approach, 627–28
Tegretol (carbamazepine): for antisocial personality disorder, 347; for bipolar disorder, 233, 617
Telephone hot lines, 674, 676, 678
Television programming: for drug and alcohol abuse prevention, 673–74; for mentally retarded individuals, 519
Temperament: in conduct disorders, 535–36; of infants, 75–76; personality disorders and, 314; phobias and, 165
Temporal lobes: damage to, 490; in schizophrenia, 468
Temporolimbic region, in schizophrenia, 468
Tension headaches, 299
Terrorist groups, 112, 130
Tertiary prevention, **668**, 678–81; aftercare programs for, 680–81; therapeutic communities for, 678–80
Test(s) (*see* Psychological tests)
Testosterone, for treatment of transsexuals, 416
Thailand, overcontrolled problems in, 109
Thematic Apperception Test (TAT), 580, **581**–82
Therapeutic communities, 678–80; for schizophrenia, 475
Therapeutic relationship, 628–30
Therapists, 628 (*see also* Mental health professionals; *specific professions);* characteristics of, 661; duty to protect and, 686–87; providing psychotherapy, 627–28; rapport with client, 570; sexual involvement with clients, 663–64; transference and, 632, 634
Theriaca, 375
Thioridazine (Mellaril), 610, 611
*The Third Report on Alcohol and Health*, 361
Thorazine (chlorpromazine), 609–10
Thought, paranoid, 478
Thought disorders: disturbances of, in schizophrenia, 449–50; in schizotypal personality disorder, 319–20
Threats: internal sources of, 283; perception of, 123, 124; suicidal, 246
Three Mile Island nuclear accident, 123
Tics, **551**
Time-limited dynamic psychotherapy, 635
TKS (taijan kyofusho), 108, 189–90
Tobacco, abuse and dependence on, 388–89
Tofranil (*see* Imipramine (Tofranil))
Token(s), as rewards, 86
Token economies, **641**–42; for schizophrenia, 475
Tolerance, **356;** of stress, 123
TOPS (Take Off Pounds Sensibly), 391
Torture victims, posttraumatic stress disorder among, 148, 149
Tourette's syndrome (TS), **551;** obsessive-compulsive disorder associated with, 188
Toxicity, **355**
Traffic accidents, posttraumatic stress disorder and, 137–38
Training, of mentally retarded individuals, 517–18
Tranquilizers: for alcohol withdrawal, 370; major (*see* Antipsychotic drugs); minor (*see* Antianxiety

drugs); for psychogenic physical illness, 305–6; for sleepwalking, 550
Transference, **633**, 634
Transference neurosis, 634
Transorbital lobotomy, 608
Transsexualism, **415–16**
Transsexual surgery, 416
*Transvestia* magazine, 408
Transvestic fetishism, **407–9**, **408**, 414

# ABOUT THE ARTWORK IN THIS BOOK

In 1945, Jean Dubuffet began collecting *art brut* (literally, "raw art"), a term he used to describe art created by people who live outside the cultural mainstream—mental patients, spiritualists, innocents, maladjusted persons, loners, and those who exist at the fringes of society. Dubuffet wanted to exhibit an art in which "creation shines in its pure state, free of all the compromises which alter the mechanisms in professionals' productions." The collection that resulted—now housed in the Chateau de Beaulieu in Lausanne, Switzerland—provides an extraordinary glimpse into the inner lives and private visions of cultural outsiders and confirms Dubuffet's sense of the profound talents that often lie within those who are, for one reason or another, considered to be abnormal. We are grateful to the museum in Lausanne for allowing us to use selected works from the collection in this text.

We are also grateful to the proprietors of the Prinzhorn Collection of the Art of the Mentally Ill at the University of Heidelberg for allowing us to reprint works from that collection, which contains some 6000 works or objects that were created by 516 patients, almost all of whom were chronically ill and many of whom had been institutionalized for most of their lives. Finally, we would like to thank the Ricco/Maresca Gallery, the Adolf-Wölffli-Stiftung Kunstmuseum, Al Vercoutere, Janice and Mickey Cartin, Galerie Karsten Greve Köln, and for sharing with us the work of artists who, for one reason or another, were or are outside the cultural mainstream.

At the beginning of each chapter, we display a work by one of the artists, along with a capsule biography. Some of the artists are known to have suffered from disorders described in the text; in other cases we lack the information to know for sure what the nature of the artist's problem was. The creators of these artworks, whatever their "diagnostic status," offer us an intriguing look into disordered human psychology.

# Feedback, please!

We need your reactions and ideas if *Abnormal Pyschology and Modern Life* is to serve you and others better. What did you like best and least? What would you like to have more or less of? How could it have been handled better? Please jot down your suggestions, cut out this page, fold and tape or staple it, and mail it to us. No postage is needed.

Many thanks!
*The authors*

*For every chapter that you read, please make a check mark on each line to indicate your evaluation of it. It is ideal if you can do this as soon as you finish reading each chapter.*
